macroscopically, and but a few cells under the microscope. The petechiæ were fading and the tonsils were much less swollen. He was bright and cheerful. Towards evening, after a normal sleep, he awoke with a slight convulsion, and almost immediately putting both hands to his head had a general convulsion, and died in a few minutes. As a postmortem examination was not permitted the cause of death could not be determined.

Antivivisection Argumentation.

The New York Antivivisection Society had a dinner on Tuesday of this week at which Mr. Stephen Coleridge, the secretary of a similar society in England, was a guest of honor and spoke in the style peculiar to his kind. He said, according to the newspaper report of the banquet, that dogs were daily being betrayed by beings that stand to them as gods, and then went on to speak of the things the antivivisectionists always picture to themselves and others as taking place in physiological laboratories. How competent he is to speak of such things may be gathered from the testimony he gave in court on one occasion, in which he said he had never seen an animal experiment and was "wholly unacquainted with the thing from personal knowledge." At the same dinner Mr. John De Witt Warner spoke of the Rockefeller Institute "where agony is distilled by mutilation and torment." Mr. Warner has written more or less on comparative mythology. The exasperating thing about antivivisectionists' charges is that they are so indefinite and general, and often so absurd in their wide departure from fact that it is impossible to refute them. As the *New York Times* says, commenting on the exhibition which the antivivisectionists have been giving in this city in preparation for the legislative campaign, "It would probably be unjust to say that the antivivisectionists know nine-tenths of their statements to be false and the remainder exaggerations and distortions. In some mysterious way they are able to convince themselves that vivisection is useless and cruel and wrong. Those assumptions made, they accept as true any assertion supporting that view and reject any evidence controverting it." It is even less possible to argue with them than with the Christian Scientists, for they are not only as foolish and as gullible, but they are, or pretend to be, even more ignorant of what scientific medicine stands for and what are its aims. They are as slippery in argument as many of them are knowingly and wilfully slanderous in their statements regarding the work of scientific investigators.

News of the Week.

Grace Hospital of New Haven, Conn., has recently, by vote of the Board of Managers, been opened to the general physicians of the city, who may treat their private patients there. Previously the use of the hospital has been restricted to homeopathists.

University of Pennsylvania.—At a meeting of the board of trustees held February 1, it was announced that the sum of $100,000 has been donated, through the influence of a medical alumnus, to the university for a chair in the Medical Department not yet designated. Dr. David L. Edsall has been prevailed upon to remain in the medical faculty, and it is to be the settled policy for heads of clinical departments to devote a considerable portion of each day to university work.

Army Supply Depot Burned.—The New York medical supply depot of the United States Army was destroyed by fire on February 4, 1910. The loss is estimated to be between $500,000 and $1,000,000. The New York depot was the most important one owned by the government for medical supplies of the army, as through it went two-thirds of all the army medical supplies. A large consignment intended for the Canal Zone was destroyed.

A New Surgeon-General of the Navy.—President Taft on February 4, 1910, nominated Surgeon Charles F. Stokes to be Surgeon-General of the Navy, with rank of rear admiral, to succeed Presley M. Rixey. Dr. Stokes is a native of New York and is 47 years old. He is a graduate of the College of Physicians and Surgeons in New York. He entered the navy as assistant surgeon on February 1, 1889. He was promoted to the grade of passed assistant surgeon on February 1, 1892. He has had the rank of surgeon since May 31, 1900. During the Spanish war he served on the hospital ship Solace, which was attached to the Atlantic fleet. He also commanded the hospital ship Relief from January 15 to December 1, 1908, while that vessel was attached to the Atlantic fleet. He is now on duty at the Naval Medical School Hospital in Washington. He stands tenth on the list of surgeons, and jumps above about forty others who are senior to him. Before entering the navy, Dr. Stokes was connected with several New York hospitals. In 1883 he was appointed an ambulance surgeon in the Chambers Street Hospital. In 1884 he was appointed house surgeon at Bellevue Hospital. From 1886 to 1889 he was visiting surgeon of the outpatient department of the New York Hospital. In 1887 he was a visiting surgeon of the outpatient department of Bellevue Hospital.

St. Petersburg Free from Cholera.—A dispatch from St. Petersburg says that the epidemic of cholera for this season is officially regarded as closed, the last cholera patient having been discharged as cured from the city hospitals. Since the outbreak of the epidemic in August, 1908, there have been 16,594 cases and 6,666 deaths, of which 7,631 cases and 2,680 deaths occurred during the year just closed.

Cocaine Sellers Sentenced.—Judge Mulqueen has imposed full limit sentences in General Sessions in New York City to two cocaine sellers who had pleaded guilty to attempting to dispose of the drug on the Bowery on January 5. Each received a year in the penitentiary and a fine of $500, with a day behind the bars for each dollar of the fine not paid. The arrests were made by detectives employed by the food and drug department of the Board of Health.

Dr. Lawrence F. Flick was the recipient of a silver loving cup from his associates on the staff of the Henry Phipps Institute for Tuberculosis at a testimonial dinner given in his honor at Philadelphia on the evening of February 1.

American Guild of St. Luke.—The second meeting will be held at Cathedral College, Fifty-first street and Madison avenue, on Wednesday evening, February 16, at 8:30 P. M. An address

will be delivered by the president, Dr. Charles E. Nammack, on "The Relation of the Doctor to the Church." Physicians interested are invited to attend.

The Johnson County (Neb.) Medical Society held its annual meeting at Tecumseh on January 20, 1910. The folowing officers were electe l: *President*, Dr. S. Howard of Elk Creek; *Vice-President*, Dr. J. W. Archerd of Cook; *Secretary-Treasurer*, Dr. A. P. Fitzsimmons of Tecumseh; *Censor*, Dr. J. W. Turner of Sterling.

The Oxford County (Ont.) Medical Association has elected the following officers: *President*, Dr. Odlum; *Vice-President*, Dr. McKay of Ingersoll; *Secretary*, Dr. Brodie; *Treasurer*, Dr. Neff of Ingersoll.

The Sanpete County (Utah) Medical Society has elected the following officers for the coming year: *President*, Dr. Steiner of Richfield; *Vice-President*, Dr. W. P. Winters of Mt. Pleasant; *Secretary*, Dr. Gledhill of Richfield.

The Sullivan County (N. H.) Medical Society, at a meeting at Claremont on January 12, 1910, elected the following officers: *President*, Dr. E. C. Fisher of Sunapee; *Vice-President*, Dr. E. P. Claggett of Newport; *Secretary*, Dr. E. M. Fitch of Claremont; *Treasurer*, Dr. David M. Currier of Newport; *Censors*, Dr. A. S. Marden of Newport, Dr. O. C. Young of Charlestown, and Dr. H. C. Sanders of Claremont.

The Associated Physicians of Long Island held its twelfth annual meeting in Brooklyn January 29, 1910. Major General Leonard Wood was the guest of honor and delivered an address. The following officers were elected: *President*, Dr. Thomas R. French of Brooklyn; *Vice-Presidents*, Dr. Frank Overton of Patchogue, Dr. William B. Brinsmade of Brooklyn, and Dr. George H. Meyneu of Brooklyn; *Secretary*, Dr. James Cole Hancock of Brooklyn; *Treasurer*, Dr. Charles B. Bacon of Blackwell's Island.

The Aberdeen District (S. D.) Medical Society met at Aberdeen January 25, 1910, and elected the following officers: *President*, Dr. Geib of Groton; *Vice-President*, Dr. Adams of Aberdeen; *Secretary*, Dr. J. B. Whiteside of Aberdeen; *Treasurer*, Dr. Gunderman of Selby; *Censors*, Dr. H. E. McNutt, Dr. E. J. Clemons of Aberdeen, and Dr. J. D. Jones of Groton.

The Fremont County (Colo.) Medical Society, at its annual meeting, held January 25, 1910, at Florence, elected the following officers: *President*, Dr. R. E. Holmes of Canon City; *Vice-President*, Dr. L. E. Rupert; *Secretary*, Dr. R. C. Adkinson.

Gloucester County (N. J.) Medical Society.—At the annual meeting held at Woodbury on January 22 the following officers were elected for the ensuing year: *President*, Dr. Cyrus B. Phillips of Pitman; *Vice-President*, Dr. J. H. Underwood of Woodbury; *Secretary and Treasurer*, Dr. G. E. Reading of Woodbury; *Reporter*, Dr. Howard A. Wilson of Woodbury; *Censors*, Dr. James Hunter, Jr., of Westville, Dr. Luther M. Halsey of Williamstown, Dr. H. A. Stout of Wenonah.

Atlantic County (N. J.) Medical Society.—At the annual meeting held January 14 the following officers were elected for the ensuing year: *President*, Dr. E. H. Harvey of Chelsea; *Vice-President*, Dr. Thomas Dunlap; *Secretary and Treasurer*, Dr. Edward Guion.

Delaware Co. (Pa.) Medical Society.—At the annual meeting held at Chester, January 14, the following officers were elected for the ensuing year: *President*, Dr. Francis N. Baker of Media; *Vice-President*, Dr. D. Forrest Harbridge of Chester; *Secretary*, Dr. C. I. Stiteler of Chester; *Treasurer*, Dr. D. W. Jeffries of Chester; *Reporter*, Dr. Walter E. Egbert of Chester.

The Adams County (Neb.) Medical Society held its annual meeting at Hastings, on January 11, 1910. The election of officers resulted as follows: *President*, Dr. J. V. Beghtol; *Vice-President*, Dr. M. W. Baxter; *Secretary-Treasurer*, Dr. E. A. Weir; *Censor*, Dr. M. W. Baxter.

The Androscoggin County (Me.) Medical Society held its annual meeting in Lewiston, on January 11, 1910, and elected the following officers: *President*, Dr. D. A. Barrell; *Vice-President*, Dr. H. S. Sleeper; *Secretary*, Dr. W. S. Garcelon; *Treasurer*, Dr. B. F. Sturgis; *Board of Censors*, Dr. R. J. Wiseman, Dr. E. V. Call and Dr. H. E. E. Stevens.

The Center District and Merrimack County (N. H.) Medical Society, meeting at Concord on January 11, 1910, elected the following officers: *President*, Dr. Arthur K. Day of Concord; *Vice-President*, Dr. A. A. Beaton of Franklin; *Secretary-Treasurer*, Dr. P. T. Haskell of Concord; *Chaplain*, Rev. W. Stanley Emery of Concord; *Censors*, Dr. A. M. Fernald, Dr. Charles H. Dolloff, and Dr. Anna M. Littlefield.

The Galveston County (Tex.) Medical Society has elected the following officers for 1910: *President*, Dr. D. H. Lawrence; *Vice-President*, Dr. H. O. Sappington; *Secretary*, Dr. James J. Terrill; *Censors*, Dr. H. R. Dudgeon and Dr. W. R. Carter.

The Hale County (Ala.) Medical Society, meeting in Greenboro, has elected officers for 1910 as follows: *President*, Dr. W. C. Gewin of Akron; *Vice-President*, Dr. S. C. Carson of Greensboro; *Secretary and Treasurer*, Dr. C. A. Poellnitz of Greensboro; *Censor*, Dr. R. J. Griffin of Moundville.

The Pierce County (Wash.) Medical Society met at Tacoma recently and elected officers as follows: *President*, Dr. J. B. McNerthney; *Vice-President*, Dr. J. H. Brown and Dr. W. D. Read; *Secretary*, Dr. E. O. Sutton, and *Treasurer*, Dr. R. A. Gove.

The Scott County (Ia.) Medical Society met at Davenport, January 12. The following officers were elected for the year 1910: *President*, G. F. Harkness; *Vice-President*, E. S. Bowman; *Secretary and Treasurer*, J. V. Littig.

The Warren County (Ky.) Medical Society has elected the following officers for 1910: *President*, Dr. F. D. Cartwright; *Vice-Presidents*, Dr. G. W. Lewis of Oakland and Dr. John H. Blackburn; *Secretary and Treasurer*, Dr. Lillian H. South.

The Barton County (Mo.) Medical Society met January 13, 1910, at Lamar, and elected the following officers: *President*, Dr. J. L. McComb; *Vice-President*, Dr. Allee; *Secretary*, Dr. Brown; *Censor*, Dr. Cromley.

The Jackson County (Okla.) Medical Society met at Altus, January 18, and held a meeting for the purpose of reorganization. The following officers were elected: *President*, Dr. J. W. Echols; *Vice-Presidents*, Dr. J. W. Wilson and Dr. A. O. Merrideth; *Secretary and Treasurer*, Dr. L. A. Hawkins.

The Holmes County (Miss.) Medical Society met in Lexington, on January 11 and 12, 1910, and elected officers as follows: *President,* Dr. W. S. Derrick of Goodman; *Vice-President,* Dr. M. L. Pollard of Thornton; *Secretary and Treasurer,* Dr. S. A. Eggleston of Lexington; and *Censor,* Dr. A. M. Newman of Acona.

The Tillman County (Okla.) Medical Society has elected the following officers: *President,* Dr. T. G. Priestly; *Vice-President,* Dr. J. H. Hansen of Grandfield; *Secretary and Treasurer,* Dr. A. B. Fair; *Censors,* Dr. Hays and Dr. Osborn.

The Fitchburg (Mass.) Medical Society held its annual meeting January 11, 1910, and elected officers for the coming year as follows: *President,* Dr. John W. Stimpson; *Vice-President,* Dr. Raymond Jones; *Secretary,* Dr. J. E. Luscombe; and *Treasurer,* Dr. C. H. Jennings.

The Waterbury (Conn.) Medical Association met January 10, 1910, and elected the following officers: *President,* Dr. John M. Benedict; *Vice-President,* Dr. Thomas J. Kilmartin; *Treasurer,* Dr. C. S. Rodman; *Secretary,* Dr. James L. Moriarty.

The Neenah-Menasha (Wis.) Medical Club was organized at Neenah recently. The officers are: *President,* Dr. J. R. Barnett, Sr.; *Vice-President,* Dr. F. M. Corry; *Secretary-Treasurer,* Dr. S. G. Todd.

The York County (Me.) Medical Society held its annual meeting at Saco on January 13, 1910, and elected the following officers: *President,* Dr. C. E. Thompson of Saco; *Vice-President,* Dr. F. E. Small of Biddeford; *Secretary,* Dr. L. L. Powell of Saco; *Treasurer,* Dr. L. E. Willard of Saco; *Board of Censors,* Drs. H. L. Prescott of Kennebunkport, E. L. Burnham of Sanford, and Paul S. Hill of Biddeford.

Obituary Notes.—Dr. William H. Taylor of Cincinnati died at his home February 6, 1910, aged 73 years. He was a graduate of the Medical College of Ohio in 1858. For thirty-six years Dr. Taylor was a member of the visiting staff of the Cincinnati Hospital. He was a member of the Academy of Medicine of Cincinnati, the Ohio State Medical Association, and the American Medical Assocaition. He was also a member and the first president of the American Association of Obstetricians and Gynecologists.

Dr. Rolin B. Gray of New York died in East Orange recently. He was a graduate of the New York Homeopathic Medical College in 1871.

Dr. William Lawrence Woodruff of Long Beach, Cal., died in that city February 4, 1910, aged 50 years. He was a graduate of the Hahnemann Medical College of Philadelphia in 1882.

Dr. Alvin Herbert Eccleston of Providence, R. I., died at his home January 23, 1910, as the result of a cerebral hemorrhage, probably caused by a minor automobile accident. He was 51 years of age. Dr. Eccleston was a graduate of the Albany Medical College in 1880 and was a member of the Providence District Medical Society and the Rhode Island Medical Society. In 1889 he served in the Rhode Island Legislature and in 1890 was a member of the State Board of Health. He was also Colonel of the United Train Artillery.

Dr. Herbert C. Bradford of Lewiston, Me., died at his home January 24, 1910, aged 77 years. He was a graduate of the Hahnemann Medical College in Philadelphia in 1857. He was for many years a member of the school board of Lewiston.

Dr. Evans E. Brubaker of Northfield, Minn., died at his home recently, aged 57 years. He was a graduate of Starling Medical College in 1878 and was a member of the Rice County Medical Society and the Minnesota State Medical Association.

Dr. James Monroe Dicks of El Paso, Tex., died in that city January 24, 1910, aged 26 years. He was a graduate of the University of Georgia in 1907 and was a member of the El Paso County Medical Society and the State Medical Association of Texas.

Dr. Charles Emerson Jones of Hartford, Conn., died at his home January 24, 1910, aged 54 years. He was a graduate of the New York Homeopathic Medical College in 1882.

Dr. Edward Raphael Joyce of Lewiston, Me., died at his home January 22, 1910, aged 29 years. He was a graduate of Holy Cross College in 1901 and of the Medical Department of Columbia University in 1905. He was a member of the Androscoggin County Medical Society and the Maine Medical Association.

Dr. Ephraim Luellen of Westfield, O., died at his home on January 16, 1910, aged 85 years. He was a graduate of the Eclectic Medical Institute of Cincinnati in 1863.

Dr. Raphael Owen Semmes of Mobile, Ala., died at his home January 21, 1910, aged 30 years. He was a graduate of the Mobile Medical College.

Dr. Augustus W. Stevens of Storm Lake, Ia., died at his home January 20, 1910, aged 79 years. He was a graduate of the College of Physicians and Surgeons of Keokuk.

Dr. Frederick A. Wright of Glen Cove, Long Island, N. Y., died January 30, 1910, in Newark, N. J., aged 63 years. He was a graduate of the Bellevue Medical Hospital College in 1871.

Dr. John B. Learned of Florence, Mass., died at his home January 24, 1910, aged 70 years. He was a graduate of the College of Physicians and Surgeons of New York in 1865. Dr. Learned was a member of the Massachusetts Medical Society and the American Medical Association and an ex-president of the Hampshire County Medical Society.

Dr. Samuel Wesler died at Philadelphia on Feb. 1, 1910, at the age of 26 years, as the result of an operation for appendicitis. He was graduated from the medical department of the University of Pennsylvania in the class of 1898 and he had served as resident physician and chief resident physician in the Mt. Sinai Hospital. He was a member of the Southwark Medical Society.

Dr. James H. F. Milton died at Philadelphia on February 1 at the age of 79 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1860. He enlisted in Co. A, 65th New York Volunteers at the outbreak of the Civil War and he was soon elevated to a captaincy, serving until the close of the war.

Dr. Francis McC. Christy of Altoona, Pa., died at Lancaster on January 30, at the age of 49 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1882.

Dr. Millson R. Allen of Norfolk, Va., died suddenly at his home February 2, 1910, aged 48 years. He was a graduate of the Hahnemann Medical College of Philadelphia in 1887, and was a member of the Virginia State Board of Medical Examiners.

Dr. Thomas F. Dunigan of Vichy Springs, Va., died at his home February 1, 1910, aged 55 years. He was a graduate of the Missouri Medical College in 1884.

Correspondence.

THE TISSUE DENSITY FACTOR IN RELATION TO ERGOT.

To the Editor of the Medical Record:

Sir:—I beg to add a few words in way of elucidation of a clouded point in Dr. Alfred T. Livingston's article on "The Peculiar Province of Ergot," in your issue of January 29. Dr. Livingston inadvertently failed to distinguish between the two varieties of muscle fiber, the striped and the unstriped. It will be recalled that authors have not heretofore granted to ergot any action upon the striped fiber. This I have had the honor of convincing Dr. Livingston and other interested medical men is an error; but instead of acting directly by causing shortening by condensation, as it does on unstriped or smooth muscle, ergot, adrenal extract, and other analogous preparations act also on striped fiber by shortening the equilibrium length of the muscle, which has the effect of increasing its functional capacity. All atonic or relaxed muscle exhibits a stretching out of its individual fibers, which constitutes simply the state of relaxation of smooth muscle, but in striped muscle it involves an extension of equilibrium length, which independently contracts and expands. In general it may be said that a muscle of extended equilibrium length is a weak muscle, and, conversely, that one of shortened equilibrium length is correspondingly strong.

The relation of tissue density to equilibrium length of muscle is very well illustrated by an ordinary rubber band, which, so long as it retains its elasticity, stretches and contracts independently of changes of the equilibrium length. The normal equilibrium length of a new rubber band is, say, two inches. This two-inch band, after use or age, becomes two and a half or three inches in length. It can be stretched to greater length, but never recovers its former length of two inches, returning to the last equilibrium length of two and a half or three inches. If this rubber band is examined it will be found to be much weaker than when of normal length. It is less dense and less thick. Striped muscle exhibits analogous features.

As either striped or smooth muscle becomes relaxed it is correspondingly reduced in density, and thus in surface tension and osmotic pressure. As substances in general are thus reduced they exhibit an increase in absorption powers, and tissues exhibit absorption corresponding to their density. For this reason pathological tissues absorb more than normal tissues, and they thus exhibit a selective power for the absorption of such medicaments as ergot, the therapeutic action of which is the condensation, the shortening of the fiber, and thus the rehabilitation of the involved muscles. This is the clinical observation of Dr. Livingston and the long list of contemporaries who have followed in his footsteps in harnessing this most potent drug for the service of man.

Tissue parenchyma (living substance) exhibits several attributes in close relation to its density. Tissues of low density exhibit not only the characters above discussed, but also corresponding hyperesthesia as contradistinguished from the normal state of sensibility of tissues of normal density. This explains the action of ergot in allaying irritabilities, insomnia, hysteria, mania, and so-called neurasthenia, which Immermann so well denominated "irritable weakness." In the reestablishment of the equlibrium of the distribution of the blood the action of ergot is attained by its exhibition of a predilection for those vascular walls which are morbidly dilated, and thus containing a disproportion of the blood, of which they are unable to rid themselves, until their greater porosity and absorbicity make them "preferred creditors" for ergot, hypodermically administered, when the dilated vessels contract down to their normal calibers, by virtue of which the excess of blood of such dilated vessels is ejected to other regions, and thus passive hyperemias cease to exist.

The action of ergot and other remedies of the adrenal extract type, as hemostatics, depends upon the basal fact that all hemorrhages by diapedesis are due to relaxed and expanded conditions of the involved tissues—in fact, to loss of the integrity of the walls of blood-vessels by virtue of pathologically excessive porosity and permeability to the blood. The counteraction-contraction produced by this type of drugs is the basis of the therapeutic action, though hemorrhage by rhexis is also more or less favorably influenced by the extreme action of this class of drugs. My own opinion is that for the forenamed purposes ergot excels adrenal extracts, but as a hemostatic and for the more transient, but perhaps prompt effects, adrenal extracts excel.

Dr. Livingston's introduction of the profession to the wider clinical uses of ergot, with all that that implies, will be appreciated by future generations as one of the crowning contributions of this age to the armamentarium of posterity.

Homer Wakefield, M.D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DOCTORS IN THE ELECTION—OATHS ACT—SCHOOL INSPECTION, FIRST YEAR'S REPORT—ULCER OF DUODENUM—HOSPITAL SATURDAY FUND REPORT—FATAL MISTAKE IN DISPENSING—OBITUARY.

London, January 21, 1910.

The general election has been the one absorbing topic all through the week. Parties are so divided and the excitement so intense that even doctors who are usually ready to sacrifice party to assist medical candidates are showing themselves as ardent politicians. Both sides are represented in the two dozen medical aspirants, about the same number that tried in the last election, of whom only half were successful. It is hoped that as many may this time, but half a dozen have already failed.

Sir William Collins and Sir Scott Robertson have retained their seats. Dr. Addison of Barts, a new candidate, has obtained a seat and should be an excellent representative of the profession. He seemed rather thin-skinned during the contest, complaining in the press that his occupation as professor of anatomy had been spoken of by his opponent as "cutting up bodies, which did not qualify him to cut up the empire." To this his opponent, whose name was Hay, replied that the doctor had previously for weeks placarded the constituency with "Vote for Brains—not for Hay."

Among the defeated candidates so far is Surgeon-General Evatt, whose earnest voice and pleasant personality will be missed by both sides. Sir J. Sherburn and Drs. Molson, Lunn, and Moon share his fate. The last named cannot be much disappointed, as it was only a forlorn hope in his case, created by a split in the opposite camp. There Lord Robert Cecil has gratified his spite, but he has greatly lost caste by his underhand methods. So has his principal supporter, Lord Ludlow, who originated a falsehood about the other candidate and after three denials had not the manliness to apologize or even reply to the challenges. The continual repetition of the falsehood in various forms reached the climax in a "last word" leaflet, which drew from the dignified and esteemed president of the Royal College of Surgeons an indignant protest against its suppresio veri and suggestio falsi which will increase the respect of both sides for Sir Henry Morris as a man; it cannot increase the respect of doctors for him as a surgeon. As for Lord Robert Cecil, when he found E. Marylebone resented crooked ways, he tried for a safe seat in Northern England. But the men of the North have grit and play the game, so they have rejected the "Hotel Cecil" and called the secretary of the caucus a "flunkey" and his obedient followers "snobs." You should understand that the caucus is the central party association and the secretary the chief whip, who announced he would use all the power of the association to force Lord Robert on the constituency on a technical point which at the same time he had decided in the opposite sense in another district.

The Oaths Act has no sooner come into operation than those who promoted it, or rather some of them, are expressing dissatisfaction with it and threatening to try to get it amended. They say the repetition of the words by the person sworn causes delay and that a mere assent to the terms recited by the officer of the court is sufficient. Some of them also object to holding a testament in the uplifted hand and declare the volume may be infected by a previous holder with some disease or other. The plan is certainly an advance on kissing the book, to which so much revulsion has been felt. In the present state of parliamentary affairs it is pretty certain that no amendment will take place for some time, during which the dissatisfied persons can watch the working of the Act.

Dr. Newman, the Medical Officer of the Board of Education, gives an account of the first year's work under the Act of 1907, which provides for the medical inspection of school children. The Act came into force on January 1, 1908, and the report shows that within the year much has been accomplished. Prior to the Act very few local education authorities had

taken any thought about medical work, but now all the 328 separate authorities are attempting to provide for medical inspection of the scholars and not a few are considering the many questions of school hygiene which have been raised by sanitarians or have been brought before them by their medical officers. Fears were expressed in some quarters lest the medical inspectors might be more or less completely separated from the public health department and so lead either to overlapping on the one hand or to friction on the other. In many ways the work of a school doctor is closely related to that of the Medical Officer of Health, *e.g.* notification of infectious diseases. In view of this a majority of the authorities have appointed their Medical Officers of Health to be their school officers also, giving him whatever assistants may be required for the additional duties thus placed upon him. In some cases a different course has been adopted, but in them an attempt to secure proper cooperation has been made and it looks as if the school medical service will develop as a subsidiary department of the State Sanitary Service. It is stated in the report that "the intention of Parliament was clearly that medical inspection should be of a practical character, and have practical rather than academic results." With this interpretation many will agree, but questions have already been raised as to how far the attempt to attain these "practical results" can be carried under the authority of the Act. Is inspection to be a prelude to treatment? And if so, are the ratepayers to be saddled with the establishment of school clinics, dispensaries, and infirmaries? Or are the school boards to arrange to pay for the treatment of the scholars at voluntary hospitals? Or ought they not rather to take proceedings to compel parents to do their duty to their children? In many cases it would seem that the relation of the scholars' condition to the sanitary state of his home must be of the highest importance—a fact evidently to be ascertained by the inspector, who would perhaps then have to pass on his information to the sanitary authority. Then in cases of poverty it would become a poor law case. But the two reports of the Poor Law Commission and the differences between the majority and minority reports have yet to undergo much discussion and the poor law service generally has to be completely reorganized.

The debate on ulcer of the duodenum was concluded at the adjourned meeting on the 11th, and I resume my analysis of the views expressed from the point where I left off. Dr. Robert Hutchison believes in hyperchlorhydria and, as I said, that it may give rise to "hunger pain," but this symptom had been marked in cases where at the post mortem there was no organic lesion of the duodenum. He admitted the need of operation in obvious cases and urged the necessity of prolonged after-treatment. Where this had been neglected he had seen disaster follow.

Dr. A. F. Hertz thought that with some reservations Mr. Moynihan's conclusions must be accepted as to the frequency of ulceration. He had no doubt that free acid was one cause of the pain, and this explained the success of alkalies in relieving it. But not the sole cause, for he had introduced several ounces of free hydrochloric acid, 0.5 per cent., into a patient's empty stomach without setting up the pain, though an operation performed soon afterward revealed gastric or duodenal ulcer. He could not recommend operation until rest in bed and careful diet for at least a month proved useless.

Mr. Paterson had operated on forty-one cases and pointed out the desirability of differentiating gastric crises from ulcer. He had not found the symptoms so typical as had been stated. Some of his patients said the pain came on immediately after food, some that it was continuous, and a few described the hunger pain.

Dr. N. Raw related a case of hunger pain in which chronic thickening of the pylorus was found, but no ulceration.

Dr. Craven Moore said hyperchlorhydria did not exist Dyspepsia might be associated with an excess of normal gastric juice and give rise to hunger pain, but this could not have the great significance that had been ascribed to it.

Mr. P. C. Childe had met with three cases in which perforation was the first symptom and so gastroenterostomy the only resource.

Mr. Moynihan, in reply, said it was generally admitted that ulcer produced the symptoms he had described, although text-books were quoted against his views by those who had not escaped from the bondage of the vocabulary. Acid dyspepsia and other misleading terms were, however, being gradually less used, and some authors were recognizing the facts which the surgeon had brought to light. The term hunger pain had been shorn of the qualities he had attributed to it. The varieties of this symptom had to be considered. By a careful study of anamnesis duodenal ulcer could be diagnosticated as accurately as any abdominal disease. Physical signs were of little if any assistance. He was confident that an ulcer which had caused protracted and recurring symptoms had reached the outer coats, and, instead of unnecessary search within, the gall-bladder and appendix should be examined when palpation and inspection did not reveal ulceration. "Appendix dyspepsia" was not at present generally recognized, but was important. If medical treatment failed in early cases, surgery should be resorted to. If the ulcer were small and single, excision would be a cure; if, as more often happened, large and multiple gastroenterostomy should be done. The precise indications were now better understood than formerly. He agreed that after the operation the patients needed supervision for some time.

The Hospital Saturday Fund collection for the year 1909 amounted to £30,708. It was a record year and shows an increase of £878 on the amount for 1908.

Death from misadventure was the verdict of a coroner's inquest in an extraordinary case which has excited much comment for the last fortnight. The doctor who supplied medicine to a patient who died after the first dose admitted that he feared he had committed the mistake of taking the solution of strychnine bottle for a chloroform one. The two stood near each other and were of the same size and shape. The other circumstances in the case make it evident that this was the true explanation and suggest various comments on the sad result.

Dr. T. D. Savill on the 10th inst. met with a premature death through an accident while traveling in Algiers. He was only 52, but had achieved a great position, both as a clinician and an author. You may remember his "System," which was written from the view of his own experience. Later he wrote much on neurology, became assistant physician to the West London Hospital, and held other appointments. His "Neurasthenia" and "Lectures on Hysteria" attracted much attention. He contributed to the societies and journals many articles and was for some time on the regular staff of the *Lancet*.

Dr. Morton Wilson died on the 6th inst., aged 43. His sanatorium was one of the first opened in England. He had been to Nordrach and it was hoped he was recovered from early phthisis. He came back and started his institution in 1900 and managed it with great skill and enthusiasm, but a recurrence of his malady has closed a promising career.

Dr. George Skene Keith, the elder brother of the late Thomas Keith, died on the 12th inst. in his 91st year. His "Fads of an Old Physician" and his "Plea for a Simpler Life" are interesting little works which aptly illustrate their titles.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

ESTHETIC ABLATION OF A BENIGN TUMOR OF THE BREAST—ABLATION OF THE SEMINAL VESICLES IN GENITAL TUBERCULOSIS—HYDATID CYSTS OF THE LIVER—TUBERCULOUS PYELONEPHRITIS WITH PRIMARY CALCULUS OF THE KIDNEY—NECROLOGY.

PARIS, December 31, 1909.

MORESTIN presented to the Surgical Society a patient in whom an esthetic ablation of a benign tumor of the breast had been performed. A small buttonhole incision was made in the upper portion of the axilla, four to six centimeters in length. From this wound to the tumor a long tunnel was worked out with a bistouri and scissors; the instruments worked beneath the skin to the neighborhood of the tumor; this was fixed with the fingers and was liberated and isolated; it was then spooned out with long forceps. This operation, from an esthetic point of view, gives an ideal result, which is to be considered in young women who must go decolleté into society, and who do not wish to show a cicatrix in a region which may be exposed to view.

The majority of surgeons consider deep tuberculosis of the genitals as inoperable, but Marion believes that

even if the operation is somewhat delicate it does not cause any immediate danger to the patient, and that we should not reject surgical intervention on the vesicles. Operation should be done in case of enlarged vesicles, and when there are fistulæ or urinary difficulties. Contraindications to operation should be bad general condition and coexistence of pulmonary lesions. There are two methods of removal of the seminal vesicles—the perineal and the inguinal. Marion prefers the perineal route, which should be employed whenever there is double vesiculitis, or vesiculitis and prostatitis. Legueu prefers the perineal route. He believes that operative indications are rare. The operation is indispensable when vesicular tuberculosis is present with tuberculosis of the testicles.

Pierre Delbet gave an interesting observation of hydatid cysts of the liver. After having resected ten to twelve centimeters of the walls of the abdomen, he incised the diaphragm and introduced his hand into the cavity and extracted the parent vesicle. To treat the large cavity he used a special procedure, consisting of aspiration of the air contained in the pocket. Having sutured the orifice, leaving only a small opening, he introduced a large aspirating needle and aspirated with a Potain apparatus. Under the influence of this procedure the liver tissue rose into position, hermetical sealing was done, and the walls sutured without drainage. The immediate results were excellent. Quenu thinks that multiple hydatid cysts of the liver are rare. They should be treated by independent incisions, followed by reunion without drainage of the pocket. Tuffier has observed three cases of multiple hydatid cysts of the liver which were treated by incision and drainage, followed by cure. Guinard thinks it preferable to puncture the cysts separately from the periphery toward the center, for there is less chance of puncturing the blood vessels or bile ducts. Exploratory puncture through the abdominal wall should be entirely prohibited, since this is blind work. Broca thinks that each cyst should be treated by a separate incision; this is the best way of avoiding complications. Auvray, after examining various statistics, thinks that the frequency of hydatid cysts varies around 20 per cent. From the point of view of treatment there are great advantages in making a separate incision for each cyst. On the contrary, there is danger in practising the opening of deep cysts through the cavity of a previously evacuated superficial cyst.

Tuffier presented the kidney of a woman of thirty-two who had a painful right kidney, while the left one was neither painful nor palpable. The diagnosis of pyelonephritis on the right side had been made. Radiography showed just above the twelfth rib a regular opacity which suggested a renal calculus. The endovesical separation of the urine with Luys' separator showed good function of the left kidney and the presence of pus only in the right kidney; the patient had a nephrectomy of the right kidney. In the pelvis of this kidney was found an irregular calculus moulded to the pelvis and calices of the kidney. Histological examination of the kidney made by Mauté showed that the entire cortical substance was infiltrated with tuberculous nodules, in which examination for the bacillus of Koch was positive. The chemical analysis of the calculus showed that it was formed of pure uric acid.

Professor Edouard Brissaud, member of the Academy of Medicine, died prematurely at the age of fifty-seven. Born at Basançon in 1852, he studied medicine at Paris. Externe, then Interne of the Hospitals in 1875, he was prosecutor for Charcot in the anatomopathological laboratory. Hospital physician in 1884, he became a professor *agrégé* in 1886. In 1899 he was called to the chair of History of Medicine, and in 1900 he became Professor of Internal Pathology. The great reputation of Brissaud came from his works on neuropathology in which he has studied not only original but compiled subjects. His fine Atlas of the Anatomy of the Brain of Man, his studies on cerebral localization, on aphasia, on the contractures of hemiplegia, and on tabes represent but a small portion of his neurological work. He was the promotor of a great medical publication, the "Traité de Médecine," which he published with Charcot and Bouchard; then with Reclus and Pinard he produced a compendium taking up all the questions of current practice, called "Medico-Surgical Practice." He had a luminous intelligence, harmonious thought, and an ironical wit that was quite original. It is but a month ago that he was taken in the midst of full health with an illness the gravity of which his colleagues at once recognized, and for which they at once called in the English surgeon, Horsley. His operation gave hopes which cruelly deceived, for Brissaud died Sunday, December 19, 1909.

Professor Malassez, Member of the Academy of Medicine, Director of the Laboratory of Histology of the College of France, President of the Society of Biology, died at the age of sixty-six years. His remarkable works on the blood are known to all. He was for thirty years a collaborator of Ranvier. He was one of the first and greatest of French histologists. He was occupied principally with pathological anatomy and with the histology of tumors especially.. Aside from these questions, he left numerous memoirs on genital lesions, tuberculosis, and parasitic affections. We may say that the name of Malassez belongs to the history of medicine for a third of a century.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 27, 1910.

Infectious Diseases and the Mouth.—W. R. Woodbury calls attention to the care now paid to the teeth and the revelation that examination of school children shows that decayed teeth is the most common defect among them. Next come tonsils and adenoids. Enlarged tonsils are a predisposing cause of diphtheria. What is true of diphtheria is true to a less extent of scarlet fever and measles. Carriers of disease among school children work much evil. The close relation of school life is a determining factor in diphtheria epidemics. Dental cripples cannot get full nutritive value from their food. Partially digested food as it passes through the alimentary canal gives up but a part of its nourishment. It clogs up the system and leads to constipation, itself an evil and a breeder of evils. Bad teeth and tonsillar enlargement are closely related. Only about eight per cent. of the community take proper care of their teeth. Mouth conditions are of practical importance in tuberculosis. In this disease the greatest importance comes through sanitation. Mouth sanitation is of the greatest benefit. To prevent the malady from gaining a foothold, and to counteract it if it once gets it, a generous amount of uncontaminated food is demanded. Tuberculosis is a chronic disease and a continual reinfection through food only partly masticated and contaminated with infection stored in a dirty mouth is a hopeless fight against an insidious foe. Food mixed with tuberculous sputum is not a wholesome diet. There are signs that a better appreciation of bodily needs in this respect is growing in the community. Preventive dentistry is attaining a just place. The careful attention now being given to the examination of school children's mouths should make an impress in the next generation. Oral sepsis is a matter of comparatively easy attainment and a thing of splendid results.

The Correlation of Digestive Functions.—This subject is discussed by W. B. Cannon, who pays particular attention to the matters of the rate of passage of the food stuffs through the alimentary canal, their alterations in different parts of the canal and the regions of absorption. Under the latter heading he says that the processes of digestion and absorption emphasize the importance of the small intestine. In it are found the enzymes that finish the work begun by the enzymes of the mouth and stomach. There they make the final preparations for the entrance of the food into the body. In the small intestine most of the food is absorbed. The only other part of the canal beside the small intestine and proximal colon in which absorption occurs is the stomach. The amount of absorption taking place here is slight. The actions of the various parts of the canal are naturally related, and appreciation of this fact naturally requires a readjustment of attitude toward digestive disturbances. Any particular pathological state can no longer be regarded rationally by itself but must be considered in its bearings on the digestive activities that naturally precede or follow it. Can the parts of the alimentary tract adapt themselves when special demands may be placed upon them? These and other similar questions must be solved by future researches. There also comes in the question to what extent the activities normal in sequential dependence may become free and unconditioned.

New York Medical Journal, January 29, 1910.

Malignant Growths of the Sigmoid and Rectum.—J. F. Erdman studies a series of 32 personal cases, 15 being males and 17 females. Of this number 13 occurred in the sigmoid, 2 in the anus and rectum, and 16 in the rectum with invasion or extension upward into the lower sigmoid while the lower sigmoid and rectum were invaded and a

distinct annular growth was also present in the sigmoid six or eight inches above the lower. The age of the patients varied from a young boy of 17 years to an old woman of 86 years. The author refers to the various operations done in the series and quotes statistics as to prolongation of life, etc. Speaking of treatment in general he says that two classes of cases present themselves, those demanding immediate relief and those in whom a time of election can be taken. In the first case treatment resolves itself into the formation of an artificial anus either temporary or permanent. In the second type of case the position of the growth with the surrounding tissues will determine the particular operation. If in the upper sigmoid excision, an end-to-end or lateral isoperistaltic or antiperistaltic anastomosis should be done. If in the lower sigmoid the formerly called intraperitoneal rectum excision is also feasible with end to end suture or if there is considerable infiltrate with difficulty in making anastomosis, a combined operation for removal with artificial anus or abdominal implantation should be done.

The New Treatment of Spastic Paralysis by Resection of Posterior Spinal Nerve Roots with Description of the Surgical Technique.—The main proposition of this paper is considered by L. Pearce Clarke while the surgical technique is discussed by A. S. Taylor. The former refers to several cases reported by Continental clinicians, and says that the motor part of the reflex arc is obviously beyond attack, for while the contraction would be temporarily relieved, a complete palsy of the muscles involved would result. Neurectomy in the peripheral nerves proper could not be employed as these consist alike of sensory and motor nerves. Even alcoholic injection in "muscle group isolation" by Schwab does not seem to be permanent or fully adequate. Hence the posterior sensory roots near the cord dorsal to their individual ganglia is the point of operation if one seeks to attack the sensory side of the arc. Even though ataxia and lost reflex irritability should supervene in the operation, this state is much to be preferred to the spastic condition which it relieves. However sufficient data are now at hand to show that neither mishap obtains in the new operation. The author reports three personal cases on whom the operation of hemilaminectomy was done by Dr. Taylor who gives the following description of his operation: The incision is made just to that side of the spinous processes upon which the laminectomy is to be done and is carried close to the spinous processes down to their bases. Large deep rake retractors are used to pull the muscles outward (incidentally stopping the hemorrhage) and a periosteal elevator is used to denude the laminæ, to which the muscles are but loosely attached, until they are exposed as far outward as the articular processes. With a Doyen saw the laminæ are divided at the bases of the spinous processes and also externally near the articular processes. With a bone forceps the laminæ are then lifted out. One may prefer to remove one lamina by means of the saw and forceps, and then to remove the others by means of special rongeurs. In this way one may obtain spaces 1.8 cm., 1 cm., and 1.5 cm. wide in the cervical, dorsal, and lumbar regions respectively. The dura is opened longitudinally, and after the work for which the operation is done is finished, it is completely closed with a continuous catgut suture. The muscles and aponeurosis are closed with chromic gut and the skin with silk. No drainage is used. By this method he has resected posterior nerve roots three times in the cervical region, the posterior roots on both sides from the seventh to tenth dorsal inclusive without damage to the cord proper, in one case, and the lumbar roots on one side in one case. These patients have shown practically no shock, and have healed promptly by primary union, even though one of them had a locomotor ataxia of some years' standing. In each of these cases the escape of spinal fluid when the dura was opened was very free but neither then nor afterward was there any appreciable effect noticeable in the patient's condition.

Chronic Diarrhea Due to Pyloric Insufficiency Successfully Treated with Hydrochloric Acid.—The patient of E. Palier was a carpenter of 54 years. He had been sick for about two years before coming under observation. He was having a few evacuations daily and was on a very restricted diet. About one hour after a test meal and several hours after an ordinary meal clapotage in the stomach could be elicited. The patient was allowed a more liberal diet with plenty of water, which had been restricted before, even small amounts of fresh vegetables to guard against scurvy. He was fitted with an abdominal belt and given hydrochloric acid ten drops in water twice daily after meals and later only after supper. A larger dose seemed to promote costiveness. The author regards the statement of Cannon that this acid opens the pylorus as wrong. This acid retards the evacuation of the stomach contents by acting on the pylorus, hence comparatively small doses may prove efficient when the exhibition of this particular remedy is indicated. In some cases of hyperchlorhydria accompanied by constipation and very painful piles nothing acts so magically to relieve the patient as a good dose of bicarbonate of soda. It causes evacuation of the bowels and relieves the painful piles which have resisted all the anodynes. The author says that many of the deductions made by investigators from experiments on animals as to the gastrointestinal tract are totally at variance with clinical data in man. We know that some patients stand in mortal fear of the stomach tube, and when they know in advance that it will be used on them, they pass sleepless nights, and it can be imagined with what an appetite they eat their test meal. Nevertheless in such people the gastric juice at the first examination may be normal, or there may be hyperchlorhydria with excessive secretion, which is not the least affected by fear and anxiety. He has examined the stomach contents of tuberculous patients who not long before had had severe hemoptysis and were in a state of extreme anxiety and depression; nevertheless their gastric secretion was not affected thereby, and in such cases he found excessive secretion, normal secretion, and achlorhydria, as may have been the patient's usual condition. The secretion of saliva is certainly decreased under such a condition, but not the gastric secretion including the secretion of pepsin. Fear, anxiety, unpleasant meals increase gastric secretion in those suffering from excessive acidity of the stomach, as such patients usually feel worse under such conditions.

Total Absence of the Adrenals.—The case of a woman dying with a combination of pleurisy, Raynaud's disease, and Addison's disease and coming to autopsy is reported by C. R. Lowe. Among the autopsy notes are the following statements: Both kidneys were smaller than normal; the weight of each was about 128 grams; they were pale and slightly lobulated; the capsule as a whole stripped very readily; but in one or two small areas adhered to minute portion of cortices. On section the cut surface was paler than normal, but the markings were distinct in cortex and medullary portions. The cortices were about half the thickness of the medullary portions. The pelvis of each kidney was normal in appearance. Around each kidney was the usual amount of perirenal fat. No trace of the suprarenal capsules could be found. (Subsequent microscopical examination of the adipose tissue at the normal site of the suprarenal bodies failed to discover any suprarenal tissue.)

Journal of the American Medical Association, January 29, 1910.

A Plea for the More Conservative Treatment of Sarcoma of the Long Bones.—W. B. Coley refers to his paper published two years ago in which he refers to the disappointing results in the surgical treatment of sarcoma of the long bones. While his results from the use of the serum at that time were also disappointing yet he has persisted in its use under a new method proposed in that paper by which he hoped to save more lives and also a certain proportion of limbs. He has added nineteen new cases to his former list so that he has now ninety cases as the basis of his present study. The facts set forth in regard to the treatment of these cases are in his judgment sufficient to justify giving up the traditional method of treating them by immediate amputation. He believes that in most cases it is safe to wait two or three weeks for a trial of the antitoxin before amputation. It was thought that time had been wasted, but he believes such cases would be fatal any way. On the other hand in probably a small number of cases a limb can be saved by preliminary use of the toxins and when early improvement is not marked operation will be rendered safer and have more promise of success than if the toxins had not been first used. Their greatest value in sarcoma, he believes, will be found in a judicious combination with conservative operative treatment. By their aid hip-joint amputation, which has been the rule in sarcoma of the femur, will give way to amputation below the trochanters, leaving a useful stump for an artificial limb. The toxins will be administered for a considerable period after amputation in the hope of overcoming the cells which are left behind and which without their use might cause local and metastatic recurrence. The same rules will apply to sarcoma of the humerus. Coming to sarcoma of the tibia, fibula, radius, and ulna, particularly of the myeloid type, he thinks we can safely substitute either curetting of partial resection, followed by a thorough course of the mixed toxins, for the amputation

and the number of successes will be much greater than with operation alone. With earlier diagnosis, correct interpretation of *x*-ray plates, and the use of earlier exploratory operations, he believes we can have better success with these conditions than has heretofore been achieved.

Human Hair Sutures.—F. B. Guthrie and C. C. Guthrie suggests the use of human hair for sutures for vascular anastomoses. Light brown hairs of medium fineness, about eight inches long, were tested as to tensile strength and found to be stronger than the silk previously employed. Experiments of reuniting the severed carotid and the carotid and jugular veins in dogs were successful, the healing being rapid. The article is illustrated.

Pasteurization of Milk.—R. G. Freeman thinks that public opinion is apt to swing to extremes on the question of pasteurization of milk, and he asks: "How safe are the raw milks now furnished as food for infants?" Tuberculosis, he thinks, may be eliminated practically from the question by well aired and ventilated stables and repeated tuberculin tests. The greater dangers are typhoid fever, diphtheria, scarlet fever, and epidemic sore throat. No system of control can protect the milk supply from a mild walking typhoid case among the employees or from virulent diphtheria bacilli in the mouth of a healthy diphtheria carrier. The precautions of frequent bacteriological examination of dairy employees needed against these diseases are hardly practicable. Even certified milk is not absolutely safe. He discusses the questions of rickets, scurvy, marasmus, etc., as caused by pasteurized or sterilized milk, and finds that with proper methods these diseases should not occur. Commercial pasteurization, consisting in heating milk to a high temperature for a few seconds, he condemns. The only safety for the consumer is to obtain his milk sweet and raw, and, having obtained it, to render it safe by the smallest amount of heat compatable with safety. A temperature of 140° F., but little higher than the temperature in which one can bear one's hand, if continued for forty minutes, with the milk in a closed nursing bottle is sufficient to kill all the bacteria we know and fear in milk, at the same time changing neither the taste nor, so far as we know, the chemical composition or the ferments of the milk. He sums up as follows: "1. There is no absolute safety in any raw milk. 2 Commercial pasteurization of milk, employed to keep it sweet until it can be marketed, should be condemned. 3. Milk is in no way injured, either in taste or by chemical change or action on ferments, by pasteurization at 140° F. for forty minutes. 4. Pasteurized milk does not cause malnutrition, scurvy, or rachitis."

Renal Colic.—Bransford Lewis gives an account of a case of right sided renal colic in a woman aged 25, resisting treatment, from ½ to ¾ grain of morphin only giving relief for an hour or two, and sleep being reduced to about one or two hours in the twenty-four. The patient was not strong enough for operative treatment and something had to be done at once. She was therefore placed on the cystoscopic table, a catheter was passed into the right renal pelvis, and 20 minims of a 1 per cent. solution of alypin injected. The pain was relieved in 15 minutes, the catheter was withdrawn, and the woman had the first good sleep she had had for several days and nights. The colic returned again the next day with lessened severity, and 15 minims of the 1 per cent. solution of alypin were injected with the same good effects. The catheter was left in the ureter and secured by adhesive plaster, emerging from the urethra and draining into a vessel between the thighs, and the nurse was instructed to inject 10 minims of the alypin solution whenever the pain recurred. This had always the desired effect, and after three days the crisis seemed to be over and the catheter was removed, all menacing conditions having disappeared. Later, exploratory nephrotomy was performed, and recovery ensued. Lewis has not seen this treatment reported by anyone else. It was easily applied and without objections on the part of the patient who was highly in favor of it after experiencing the relief it afforded. The release from pain seemed to have a good effect on the renal secretion which increased from 15 ounces during the painful period to 35 or 40 ounces. The alypin, he asserts, caused no depression or other bad effect.

Pseudoperitoneum, Etc.—A. F. Hertzler says that his researches have convinced him that the cell is not primarily the active agent in the formation of fibrous tissue, but that the initial processes are chemical and are identical with those of blood coagulation, the cell playing an entirely secondary part. His studies have been mainly in the formation of fibrous tissue in wound healing, especially wounds of the peritoneum, and he describes his findings in some detail. The cells, he says, appear to play no part in the formation of the exudate and its conversion into fibers, for these processes may take place before the appearance of any cells whatever. The membrane which forms over any foreign bodies stitched to the peritoneum is produced in this way and, though identical with the peritoneum in structure and function, is entirely distinct from it. This he calls the pseudoperitoneum. If it is kept in mind that such coverings are really peritoneal the expression "tearing up adhesions" will not be heard so often. Properly planned, the removal of such membranes or of the foreign body beneath them can nearly always be accomplished without leaving a surface denuded of peritoneum. The pathological conditions in which this pseudoperitoneum is formed, simulating the action of a foreign body in the experiment, are noted. The purulent exudate about a gonorrheal tube is an example. Closely resembling the preceding in appearance, though very different in its pathogenesis, is a condition of the peritoneum in which the chief changes are in the blood-vessels, which he calls varicosity of the peritoneum. The peritoneal and omental vessels, as distinguished from those of the mesentery, are the ones involved. The peritoneum appears as a veil of blood vessels which obliterate more or less the anatomical structure beneath. The causes may be active and inflammatory or obstructive processes, or in some cases, and these are the majority, no prominent causative factor is apparent. The pathology is expressed in a hyaloid degeneration of the subperitoneal connective tissue, and the most pronounced symptoms are due to splanchnic irritation manifesting itself at the peripheral nerve plexus or at the ganglia or in a pronounced splanchnic neurosis. The treatment is dependent on the etiology. If, as in most cases, an affection of the appendix in the cause, removal of the latter may be sufficient. If the changes in the vessel walls are permanent the obliteration of the vessels may be required. A third condition mentioned by Hertzler is that described by Virchow under the term *Mesenterialschrumpfung*. The process is an increase, with subsequent contraction, of the connective tissue of the mesentery, and Hertzler calls it sclerosis of the mesentery. In the beginning the condition is a subperitoneal process. Hertzler speaks of the importance of a proper comprehension of these pathologic processes of the peritoneum and the underlying structures. The pseudoperitoneum, being an adventitious product, may be mischievous and require removal or, on the other hand, it may be performing a useful function, and which of these is the case must be determined before it is attacked. In any event, these pseudoperitoneums are not to be "torn up," but are to be dealt with as peritoneum with the object of preventing the reformation of mischief makers equal to those originally existing. The varicosities are the expression of a lesion elsewhere, the removal of which may cause a cure. If not, an obliteration of the lumen of the vessels must be brought about, but this must not be done by the removal of the entire membrane involved, as the condition is not a pseudoperitoneum. In the third type, the mesenteric sclerosis, if obstruction of the lumen is caused, a resection of the intestine will be necessary. If the offending tissue is band-like, subperitoneal section of such bands will be possible if the peritoneum is intact. These three conditions may not always be easy to differentiate and the surgeon's ability and knowledge of anatomy will be his guide.

The Lancet, January 22, 1910.

Four Cases of Congenital Acholuric (So-called Hemolytic) Jaundice in One Family.—The cases are reported by F. P. Weber and C. Dorner who refer to previously reported instances. Their own patients were a man of 53, a daughter of 32, another daughter of 13, and a son of 12. Jaundice seems to have been prevalent in the family connection. It appears also to have been congenital in the four patients. In all the spleen was enlarged. In none did the urobilin test in the blood give a positive result. The red cells appeared normal and rarely of a crenated shape. The blood viscosity was within normal limits. Bilirubin was always present in the blood serum and plasma. The feces were always well colored and the urine nearly always free from bilirubin. Except during exacerbations the patients had good health and were of full physical stature. This disease is supposed to be due to a peculiar congenital abnormality or an imperfect development of the bone marrow which manifests itself by some imperfection in the quality of the red cells. Probably they are destroyed more rapidly than they should be in the normal hemolytic processes of the body. Very decided anemia is not invariably present. In some instances the jaundice is intermittent instead of remittent. Subjective symptoms are often absent. There may be, however, abdominal pain, general depression, drowsiness, increase of jaundice, moderate fever, and paleness of the face. All the symptoms appear to be more pronounced in the acquired cases in adults. Occasionally

a chlorotic type of anemia is associated with the condition. As regards treatment there does not seem to be anything very definite known. In conditions of marked anemia iron should be given and especially in early life the patients should be protected from great cold. Detailed statements are given as to the blood conditions in the four cases.

Glare, Its Causes and Effects.—J. H. Parsons says that in most instances glare is caused by strong light reflected upward from the ground or sea. In most cases only feeble diffuse light enters the eyes for the source of light is high above the observer and the eye is protected from direct rays by the overhanging brow. The organ possesses a protective mechanism in the iris. In the milder forms of the condition we experience not pain but only discomfort. Pain is regarded as invariably due to the stimulation of certain afferent areas, the nerves of common sensation. The effects of glare may be mild or severe. With the greatest degree of intensity there is a scotoma and this may later be associated with anatomical changes in the retina pigmentation in the macular region, etc. Prolonged exposure to bright light in the tropics and at sea is not infrequently followed by night blindness. These cases thus show the effects of retinal exhaustion. It is almost certain that in these cases the retinal exhaustion is due primarily to the bleaching of the visual purple which is not restored with the usual rapidity. These changes in the purple are chemical in character and might be expected to be induced most readily by the most actinic rays of the spectrum, viz., the ultra-violet rays. These are known to be responsible for "snow-blindness," but this is a superficial inflammation of the mucosa covering the eye.

Acute Cerebrospinal Meningitis with Severe Choreiform Movements.—A case is reported by J. P. Johnson whose patient was a colored boy of 15 years, who died after an illness of 60 hours' duration. At first typhoid with severe brain symptoms was suspected. After a day or so there was an almost constant choreiform movement of the arms and legs. The limbs were constantly flexed and extended and the arms were frequently crossed in a purposeless manner on the chest. The movements were so excessive that it became necessary to bandage the feet and elbows over cotton wool to prevent ulceration at the heels and elbows. Lumbar puncture was performed and some faintly turbid fluid slowly oozed out. He died with rapid pulse, stertorous breathing, and rising temperature. Autopsy showed the brain soft, the dura bound down to the underlying cortex over a circular area about four inches in diameter, the center of which corresponded roughly with the mid-point of the longitudinal fissure. Pus was found along the larger blood-vessels and in the sulci of the convex surface of the brain. There was no actual pus on the surface of the convolutions, but the pia here was injected. This injection and presence of pus were most marked over the area corresponding to the adherent dura mater which included the upper half of the Rolandic area on both sides. It was probably this condition that produced the choreiform movements. In the fluid obtained by lumbar puncture the cellular elements consisted of a few lymphocytes and a large number of polymorphonuclears. Several deeply stained cocci were found, for the most part lying in the faintly stained protoplasm of the polynuclears in groups of from one to four pairs although diplococci were also found lying free. Examination revealed a pure culture of Weichselbaum's *Diplococcus intracellularis meningitidis.*

British Medical Journal, January 22, 1910.

The Blood-Tight Uterus.—G. H. Peake reports the case of a woman with retained placenta. He had no difficulty in removing it, but the womb did not contract after its removal. He expected a hemorrhage, but none came. The organ at first seemed like a leathery bag in which the hand moved freely. What struck him forcibly afterward when washing his hands was that he had unusual difficulty in cleaning them, having to peel off thin strings of blood clot which adhered firmly to them. It occurred to him then that as there was no muscular contraction to close the blood vessels the absence of bleeding must have been due to this sticky condition of the blood. Probably clots had already been formed in the uterus before the detachment of the placenta. Was this hemostatic power, he asks, accounted for by the increase of leucocytes and fibrin known to exist during pregnancy or is there at term some blood constituent produced perhaps at the placental site which favors coagulation?

Ulceration of the Face and Fauces Treated by Bacterial Vaccines.—J. C. McWatters reports the case of a man of 34 years who presented himself with an ulceration of the face, a sore throat, and a discharge from the ear. He had fumigated a room with carbolic acid a few weeks before and following this the ulcers had appeared and had run a chronic course, having lasted some six months. Staphylococci, streptococci, and the pseudodiphtheria bacillus were found in one of the ulcers on the lip. The usual vaccine treatment was instituted and the man recovered. It was some time before the causal relation of the carbolic acid use to the lesions was suspected. The lesions resembled those of syphilis, but a Wassermann test was negative. The first vaccines improved his condition but they failed to drive out two of the invading organisms. The streptococci continued until treated by an autogenous vaccine. The only local applications used were frequent bathings with a lotion containing sodium citrate 1.5 per cent. with common salt 2.0 per cent. At night the ulcers were covered with small dressings dipped in the same solution. The sequence of changes in the tissues was probably as follows: A chemical injury of the superficial layers of the skin and fauces producing a local reduction of natural immunity which was followed by invasion of the organisms which happened to be present. This soon led to a lowering of his general immunity from absorption of toxic products resulting in a chronic course till a rising tide of general immunity was set up by the inoculations of the specific vaccines. The condition in the ear was probably due to extension of the pseudodiphtheria bacillus through the Eustachian tube, from the fauces and nasopharynx. There was no use of antiseptics during the treatment.

Vaccine Treatment in Pyelonephritis.—C. F. Routh reports the case of a young married woman of 30 years, with one child seven years old who for many years had suffered from chronic constipation and an irritable bladder. In June, 1907, she had an attack diagnosed as appendicitis, which afterward proved not to be. In June, 1908, she again became pregnant and in October had another attack supposed to be due to the appendix. Some months later she had an attack believed to be severe pyelonephritis due to *Bacillus coli* and possibly complicated with some old-standing trouble. Examination of the urine showed this view to be correct. She was given a vaccine prepared from this organism, hexamethylamine, small doses of morphine, and a nightly purge. Her symptoms continued for some time and severe rigors were present. The vaccine dose was gradually increased and was given every eight days until six doses had been administered. On the last day of February a healthy child was born, the labor being in every way normal. The patient made an uninterrupted recovery and six weeks later the urine was free from pus. The disappearance of the old kidney pain and bladder irritation led the author to believe that mild poisoning from *B. coli* may have been present for many years. At the onset of the illness the previous attack and the character of the pain made the diagnosis very doubtful and even when the presence of pus in large amount in the urine pointed to definite trouble in the right kidney her history of many years' pain in that organ made the case still obscure. The chief point of interest was the rapid improvement in the patient's general condition after the first injection of vaccine though all other symptoms remained as before until her delivery, after which they rapidly disappeared.

The Treatment of Gonorrheal and Mixed Infections of the Female Genital Tract by Lactic Acid Bacilli.—D. Watson uses the *Sauercultur* made from skimmed milk. Filtration separates the casein and leaves a slightly opalescent whey containing lactic acid bacilli in large numbers as well as lactose, lactalbumen, and salts. The solution can be increased in strength by the addition of sugar of milk and if desired by a powdered tablet of lactic acid bacilli. The local parts are thoroughly disinfected and curetted if necessary, and after the removal of all excess of the disinfectant the lactic acid is introduced into the vagina. The first effect of the treatment may be an increase of discharge, the purulent appearance of which soon ceases and it becomes white and thin. This is removed by gentle swabbing with dry wool through a speculum. In most favorable cases the secretions are normal in a few days. Sometimes two or three weeks are required. Even cases in which the tubes are involved seem to benefit by the treatment and can be discharged from observation earlier than before. Many patients are met with in general practice in whom treatment is called for on account of a purulent vaginal discharge. In the author's experience the majority of them respond to the treatment detailed. As regards the use of the lactic acid bacilli for discharges from the male urethra remarkable results have been obtained in two cases in the author's experience, but he has had no further opportunity for observation. He finds that this treatment keeps down the number of patients in the

hospital for women under his observation. He has had disappointing results with the usual antiseptic methods of treatment. He has tried douching, vaginal swabbing, and when the internal os was patent, curetting and cauterizing the uterus followed by careful drying.

Berliner klinische Wochenschrift, January 10, 1910.

Appendicitis in the General Hospital at Malmö, Sweden.—Bauer has analysed 1361 cases of appendicitis occurring in his hospital since 1896, with a mortality of 5.1 per cent. He concludes his article by saying that the mortality in acute appendicitis can and must be reduced. This may be accomplished by the following means only: (1) The public must be given a knowledge of the symptoms of appendicitis. (2) A physician must be called to every patient with appendicitis as quickly as possible. (3) The patient must be sent to the surgical division of the hospital as soon as possible. (4) Every case should be operated on as soon as the diagnosis is established, unless there is some definite contraindication, or unless in mild cases the patient and his relatives after the situation has been explained to them decide upon expectant treatment.

Lesions of Motion and Reflex Activity in the Palate, Pharynx, and Larynx in Hemiplegics.—Graeffner has examined the mouth and throat in a large number of cases of nervous diseases of different kinds. He summarizes his findings as follows: (1) Among hemiplegics one finds frequently gross lesions of motility of the soft palate, more rarely of the larynx. (2) The loss of motion occurs usually, but not always, on the paralyzed side. (3) Isolated paralysis of the contralateral vocal cord is associated, provided no extra cerebral complication exists, not with a cortical but with a bulbar affection. (4) Tremors and ataxia of the vocal cords follow apoplexy much more rarely than tabes or multiple sclerosis. (5) The irregularity and variability in the direction of the uvula as it often occurs in the healthy cannot be considered as a sequel of apoplexy. (6) The loss of the reflex or reduced reflex of the palate, pharynx, and larynx is valuable as a symptom of disease.

Deutsche medizinische Wochenschrift, January 6, 1910.

Concussion of the Brain.—Trendelenburg discusses at length the differential diagnosis between concussion, contusion, and compression of the brain, and says that these conditions are rarely found singly, two or more usually being combined. The cardinal symptoms of concussion are the sudden coma, slow pulse and respiration, and loss of pupillary reflexes. Recovery simulates that from a narcotic or alcohol. In cerebral compression, usually from hemorrhage, the onset is slower and progressive, with localizing symptoms as convulsions or paralyses, and rapid recovery after operation. If the compression is due to a depressed fracture and not to hemorrhage it may be impossible to differentiate between it and concussion. In cerebral contusions there are usually clonic motions and tonic contractions of the extremities. The symptoms may be masked by those of concussion. Flaccid paralyses are rarer than in compression. In these cases the coma does not clear up, the temperature rises rapidly, and the patient dies in coma. At autopsy small capillary hemorrhages are found in the cortex. The most characteristic symptom of concussion is the immediate coma, gradually clearing up and leaving no after effects. In mild cases the patient may not become unconscious, simply for a few moments everything becoming black before the eyes. From these cases there are all grades to those in which the coma lasts for two weeks. Vomiting is another common symptom. Retrograde amnesia is a constant symptom of concussion. This may include only the moment of the accident, or may go back several days. It gradually disappears during recovery. Concussion may be called "traumatic narcosis." The pulse is slow and the temperature subnormal. In many cases after the recovery from the unconsciousness there is a marked reduction in the memory. In some instances there occurs a condition resembling somnambulism in which the subjects do their work for several hours, but know nothing of what they have done. Psychoses may occur, including hallucinations, fixed ideas, and delirium lasting for a few days and closely resembling alcoholism. Glycosuria and polyuria are not infrequent sequelæ of concussion. The retrograde amnesia differs from ether or chloroform anesthesia, but resembles carbon monoxide poisoning or strangulation. The physiology is discussed at length. An important point is that the intensity of the concussion is, within limits, in inverse proportion to the severity of the injury causing it. When the skull is fractured, concussion is not apt to occur. There are many theories as to the cause of concussion, none quite satisfactory. Increased intracranial pressure, rupture of capillaries, and cerebral anemia have been claimed as the immediate cause, but they do not explain the symptoms. Concussion of the medulla and cord, causing immediate transitory complete paralysis, has been described, but the author has never seen such cases. Peripheral nerve paralyses, due to a blow or pressure, are common; also sensory symptoms from the same cause. The name of acute cerebral compression has been advocated for the condition, but as it is not proven that the symptoms are in reality due to such a condition the author believes in retaining the name of concussion until further study teaches the real nature of the process.

Concussion of the Brain.—Windschied discusses the subject from the viewpoint of the neurologist. He says that the process is due either to a circulatory change or to an injury to the brain as a whole. The various theories are discussed. In considering the symptoms the author says the main ones are the unconsciousness, the bradycardia, and the vomiting. The symptoms of a pure concussion are entirely nervous and functional. The most important nervous sequelæ are discussed. The most characteristic is the loss of memory, especially of names and numbers, and easy exhaustion of the mind. The second is an increase of the irritability and anxiety. Most patients complain of headache, dizziness, mental weakness, and tinnitus, and all have an intolerance to alcohol. The reflexes are usually increased; the hands tremble; there is loss of power in the extremities; there is increased cardiac instability, and loss of vasomotor control. The author calls attention to the similarity between these symptoms and those of arteriosclerosis. He does not think that the injury causes the sclerosis, but says that a mild degree of sclerosis may exist without symptoms, as the regulating mechanism of the cardiovascular system may maintain the circulation intact. He believes that in such a condition that the injury may destroy the balance of this regulation, with the resulting appearance of symptoms in an arteriosclerosis which previously gave none. The greater part of the patients developing symptoms following accidents are at the age at which arteriosclerosis is in the process of development, and most of them give a history of hard work and alcoholism. The differentiation from accident neuroses is difficult, as one condition merges into the other. The reality of the so-called post concussion psychoses is doubted by the author. He believes that they are the result of other factors than the concussion *per se*.

Elevation of the Pelvis in the Treatment of Cecal Fistulæ.—Schmiz says that to promote healing of cecal fistula or artificial anus the pelvis should be elevated. This is purely a matter of mechanics. The intestinal contents at the iliocecal valve are decidedly fluid or may at least be made so by proper attention to the diet. By raising the pelvis the valve is raised above the cecum and the ascending colon, and the intestinal contents by their own weight flow through the colon, rather than through the fistula. As a result of this the utilization of the food is not decreased; water is not drained away from the body; the formation of granulations and the healing of the wound progress with less interruption; the skin in the neighborhood of the wound is not irritated and eczematous; the dressing remains cleaner and does not require such frequent changing; and, finally, the bad psychic influence, so often found affecting patients with fecal fistulæ, is absent. The author reports a case in which this method was successfully employed.

Rectal Instillation for Pylorospasm.—Rosenstern discusses the suggestion of Rosenhaupt (MEDICAL RECORD, Vol. 76, page 822), that the rectal injections of saline solutions in cases of pylorospasm of infants had a curative action by decreasing the gastric acidity and thus relieving the spasm. The present author has been using the method for two years. His method consisted in fixing a tube in the rectum by means of adhesive plaster, and so regulating the flow of solution that from 30 to 40 drops entered the rectum per minute. The instillations were made twice a day, and each treatment lasted two hours, thus allowing about 500 c.c. of fluid to enter. The solution used was Ringer's solution, namely, sodium chloride, 7.5 gm.; potassium chloride, 0.42 gm.; calcium chloride, 0.24 gm.; water, 1000 c.c. While this method was first used merely to reduce the loss of water, the effect upon the vomiting was so striking that a further study of the subject was made. Four cases are reported. In all four cases there was a prompt effect upon the vomiting, and in three of them an immediate gain in weight. The author strongly recommends the use of rectal injections for their direct effect upon the vomiting.

Book Reviews.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By J. Nevins Hyde, A.M., M.D., Professor of Dermatology and Venereal Diseases in the University of Chicago, Medical Department (Rush Medical College). New (eighth) edition, thoroughly revised and much enlarged, with 223 engravings and 58 full-page plates, in colors and monochrome. Philadelphia and New York: Lea & Febiger, 1909.

The eighth edition of this book is distinctly welcome to student and specialist alike. Long acknowledged as one of the leading authorities on dermatology, the new edition needs description rather than praise. The work shows the greatest care in the new revision, which has been so complete as to necessitate its increase in size to the extent of 250 pages. The diseases of the warm climates have been considered in a separate chapter. New articles have been written on the following subjects: Prurigo nodularis, several forms of erythema, the fourth disease, paraffin prosthesis, osteoma and calcification of the skin, meralgia paresthetica, acrodermatitis pustulosa hiemalis, lichen spinulosus, keratolysis exfoliativa congenita, lipoma, Fordyce's disease, causalgia, leukemia and pseudoleukemia cutis, tinea ciliorum, and the brown moth dermatitis. Illustrations are probably of more importance in works on dermatology than in those on any other branch in medicine. This has been appreciated by the author, and in the present edition he has added twenty-four new plates and 120 new engravings, more than doubling the number found in the last edition. These are of exceptional excellence, showing the details of the lesions with almost startling vividness. The text is clear, concise, and well arranged. The type is good, and all the details of the bookbinder's art are well attended to.

A System of Medicine. By Many Writers. Edited by Sir Clifford Allbutt, K.C.B., M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College; and Humphrey Davy Rolleston, M.A., M.D., F.R.C.P., Senior Physician St. George's Hospital, Physician to the Victoria Hospital for Children, Sometime Fellow of St. John's College, Cambridge. Vol. VI., Diseases of the Heart and Blood-Vessels. London: Macmillan & Co., Ltd.; New York: The Macmillan Company, 1909.

This volume differs from the corresponding volume of the first edition in containing articles on the heart and vessels (including the lymphatics) only, bringing them together from the two volumes formerly containing them, and excluding consideration of diseases of the muscles and nervous system. The volume contains much new matter necessitated by the new knowledge of the heart and its working, founded upon the discoveries of Kent, His, and others, and developed largely by Mackenzie. The introductory article is on the "Physics of the Circulation," written by Professor Sherrington and extensively revised and elaborated by Dr. Mackenzie. This, if not the most important in a practical sense, is by far the most interesting article in the volume, introducing the reader to the new views of the action of the heart and of the blood circulation and explaining the principles upon which the modern science of cardiology is based.

Following this are the sections on "Diseases of the Heart," divided into twelve articles, and on "Diseases of the Blood-Vessels and Lymphatics," in six articles. The new articles, in addition to the introduction, which is practically new, are on Stokes-Adams' disease, by Osler and Keith, and on aneurysm, by Osler. The article on "Overstress of the Heart" has been rewritten, and contains an interesting section by Dr. R. W. Michell on the effect of school and university athletics on the heart of a young man. The article is full of warning against excess in athletics, and the reader will hardly agree with the conclusion of Professor Allbutt that "the importance of muscular effort as a factor in cardiac injury has been much exaggerated." The article itself, the part written by Allbutt as well as that by Michell, shows that muscular strain is a very serious factor in producing cardiac injuries which may cripple the subject for life, and the blame for it cannot be put entirely, or even largely, upon "publicity and the patronage of the vulgar press," as Allbutt would have it. The only American contributor to the volume, now that we have lost Osler, is Welsh of Johns Hopkins. He wrote the articles on thrombosis and embolism in the first volume, but, as he "was at the last moment unable to revise his standard articles, this has been undertaken while the volume was going through the press by one of the editors" (Dr. Rolleston). The articles are excellent, but how much of this excellence is to be credited to the original writer and how much to the editor we are unable to say.

With this volume the strictly medical part of the work is apparently concluded, for the remaining volumes, if the scheme of the former edition is followed, will be devoted to diseases of the nervous system. These will no doubt be valuable, and the subscribers to the work will congratulate themselves on possessing them, but it is a question whether neurology is not now so strictly a specialty as not to be considered a part of internal medicine. One may, therefore, at this stage pass judgment upon the work as a guide to the internist, and this judgment can but be favorable. There have been some things to criticise in the arrangement of the volumes and the grouping of the diseases, such as including tuberculosis among the diseases of the lungs, and also in the treatment of some of the individual articles, but, taken as a whole, we have naught but praise for the treatise. In its therapeutics, the truly essential part of any work on medicine, it is distinctly hopeful and free from the taint of pessimism, from the blight of which present-day medicine is, fortunately, emancipating itself. The reader feels that his teachers look upon medicine as the science of healing, and not solely or chiefly as pathology; the laboratory is given its proper place as a valuable aid to diagnosis, but it is not made the end and all of medical study and practice. The reader finds all that he demands—etiology, pathology, and diagnosis, and especially therapeutics. With this excellent system of internal medicine he has what he needs to equip himself, so far as books can help him, for the practice of his profession and the cure of the ills of his patients.

Collectanea Jacobi. By A. Jacobi, M.D., University of Bonn (1851); LL.D., University of Michigan (1898), Columbia (1900), Yale (1905), Harvard (1906); Professor of Infantile Pathology and Therapeutics, New York Medical College (1860-1864); Clinical Professor of the Diseases of Children, New York University Medical College (1865-1869); Clinical Professor of the Diseases of Children, College of Physicians and Surgeons, Columbia University (1870-1899); Professor of Diseases of Children in the same (1900); Emeritus Professor of Diseases of Children in the same (1903); Consulting Physician to Bellevue, Mount Sinai, the German, the Woman's Infirmary, Babies', Orthopedic, Mintern, and Hackensack Hospitals, etc., etc. In eight volumes. Edited by William J. Robinson, M.D. New York: The Critic and Guide Company, 1909.

For a period of well over a half century the name of Dr. Abraham Jacobi has been recognized in America and the world as that of a leader in medicine and in medical progress. Though he has written no text-book, his writings have appeared in scattered form year by year in the medical journals of America and Europe. These have now been collected, arranged, and edited, and fill the present eight volumes of the "Collectanea." Volumes I., II., and III. are devoted to Dr. Jacobi's special field of pediatrics. Volume IV. contains articles upon the general subject of therapeutics. Volume V. is a collection of articles on pathology, especially the pathology of the child, and contains many of the author's earliest contributions. Volume VI. is entitled "Medical Addresses." These are largely formal orations made as a retiring president of a society or as a delegate to a congress or convention. Volumes VII. and VIII. are filled with the miscellaneous addresses and writings which have been prepared for commencement exercises, the laying of cornerstones, presentation of rewards, opening of hospitals, banquets, and all of the varied occasions when it becomes necessary for a man in the public eye to speak upon subjects but remotely appertaining to his profession. The entire series of eight volumes makes up a set of books of exceptional interest. Not only do they contain a huge mass of facts of clinical importance, but they give in a straightforward manner the thoughts of a thinking man as they have been evolved over a period of half a century. They are not recollections modified by time, but the thoughts of the moment, though that moment may have been several decades ago. As a panorama of medical development during the past fifty years the series has especial interest to all who are interested in medical history. The work of the editor, Dr. William J. Robinson, has been well done. The selection of articles has been careful, and the alterations from the original forms in which the papers appeared have been judiciously slight. Old spellings, old phraseology, and old terminology have been carefully retained, and the reader is carried back many years to the days before asepsis and before bacteriology, and then brought down, through the various steps of a long life, to the immediate present, even to the politics of the last gubernatorial election.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Omaha, Neb., December 20 and 21, 1909.

THE PRESIDENT, DR. ARTHUR L. WRIGHT OF CARROLL, IOWA, IN THE CHAIR.

Gastrointestinal Surgery.—Dr. THOMAS C. WITHERSPOON of Butte, Montana, called attention to an occurrence which he believed threw some light on the question of paralytic conditions observed in the stomach and bowels, and reported the following case as an illustration. A man, previously healthy, except for gastric symptoms, wiry and active, suffered from gastric ulcer of a chronic type. The ulcer was not situated in the pylorus, but to the left, and there was no obstruction to outflow from the stomach, nor was there dilatation. Eight days after a gastroenterostomy the stomach became acutely dilated until its lower curvature reached the pelvic cavity. A second operation, done because of the dilation, nine days after the first, proved the duodenum was normal; the bowels were flat, the gastrojejunal openings were still patulous, and there was no point of obstruction beyond the stomach which could be discovered. There was also no evidence of inflammation of the stomach or intestinal wall or peritoneum. A gastrostomy was performed and the fluid in the stomach had to be removed by pumping it out, as the stomach was completely paralyzed. The original incision in the epigastric area was not healed after eight days. It opened without instrumentation immediately upon snipping the stitches at the second operation. On the ninth day this man suffered considerable pain in the stomach area and behind to the left. Following the gastrostomy the pain ceased. The epigastric incision through which both operations were done was closed at the second operation by through and through silkworm gut stitches and healed without the slightest inflammatory reaction. The conclusions to which he came after observing this case were: "(1) The acute dilatation was the direct result of a paralysis of the stomach wall. (2) The lack of healing in the epigastric incision following a careful closure at the time of the first operation, and not associated with an evidence of infection, must be attributed to a trophic disturbance. (3) The stomach and epigastric abdominal wall are both innervated by the same spinal segment. It is a matter of logical deduction that the central apparatus was responsible for disturbance in both stomach and wound. (4) Some toxic agent only could have become so rapidly operative after eight full days of a normal condition following the operation, and this agent must have produced its effects by acting upon the ganglionic nerve cells in the spinal segment. (5) This toxic agent most probably took its origin from an abnormal fermentation within the bowel or the liver failed to render harmless some product absorbed from the bowel lumen."

Dr. LEONARD FREEMAN of Denver, Colo., doubted the absence of mechanical cause in addition to the action of the bacteria on the nervous system. They knew that there were certain individuals who had stomachs that were difficult to empty, due, perhaps, to a sagging of the intestines, large and small, particularly the large intestine, in pulling down upon the stomach and to a certain extent influencing the pylorus. Such cases occurred once in a while and accounted for many difficulties in the emptying of the stomach. He thought if they were to trace these cases of dilatation of the stomach, they would probably find in the stomach of those people who had such dilatations some difficulty in the emptying of the stomach originally.

Dr. CLIFFORD U. COLLINS of Peoria, Ill., said that Madelung some years ago reported a number of cases in which separation of the abdominal incision had occurred and came to the conclusion that the kind of suture material used for closure of the wound had nothing to do with the separation. Emil Ries a few months ago reported three cases in which separation of the incision had occurred. The separation began at the peritoneal layer, and was gradual until the skin was reached, the latter being the last process in the separation.

Dr. CHAS. H. MAYO of Rochester, Minn., said a great many more cases of dilatation of the stomach occurred than was generally believed, and he would recommend the more frequent use of the stomach tube.

Dr. I. B. PERKINS of Denver, Colo., said all knew that it was usual to have considerable nausea following anesthesia; for several years he had made it a practice to put the patient in the high Fowler position, and he found in that position patients had much lass nausea, they could take water freely, and it passed readily into the intestines, and there was much less dilatation of the stomach in these cases. He had had occasion to experiment a little on himself in this line. He took an anesthetic to determine whether or not it was the psychic effect of position or whether it was due to his theory of drainage. At any rate, he had had no nausea after he was put in the Fowler position.

Dr. CHAS. H. WALLACE of St. Joseph, Mo., stated that he thought they all agreed that the failure of union of abdominal incisions, or incisions anywhere, was due to sepsis, no matter whether the sepsis was preoperative or postoperative. There was another condition which he had encountered two or three times in the failure of union of the abdominal wall, which he thought was a factor in these cases, and that was the condition of the blood of the patient before operation. He recalled two cases in which there was pronounced anemia, although operation was imperative, and there was failure of union of the incision, evidently due to the general anemia that existed. Of course, this failure of union occurred in other constitutional dyscrasiæ, such as chronic nephritis.

Abdominal Contusions, with Special Reference to the Indications for Early Operation.—Dr. L. W. LITTIG of Iowa City, Iowa, reported four cases of contusions of the abdomen with a view to giving the indications for early operation. The author quoted Hertle, who said that 52 per cent. of the patients recovered when operated upon within the first six hours; 46 per cent. when operated upon during the second six hours; 21 per cent. when operated upon during the second twelve hours, and but 7 per cent. when operated upon during the second twenty-four hours. A history of the accident, the shape of the vulnerating body, and the direction of the blow were of considerable value. Blows directed toward the spinal column were more apt to result in rupture of the intestine then blows which were slanting and which were directed away from the spinal column. After discussing the symptoms and diagnosis of abdominal contusions, the author said that if there was a contusion of the abdomen and if the muscles were rigid, one should operate. Patients might be seemingly well for a number of hours or even days, and that injury to the mesentery might result in gangrene of the intestine and death. Given a case of abdominal contusion, followed by board-like rigidity of the abdominal muscles, which did not disappear quickly, a laparotomy should be performed immediately. This symptom might be absent during shock in the absence of pain, but its absence under these conditions must not be regarded as a favorable symptom. There might be some cases in which necessity for immediate operation was not clear. There would be other cases which did not seem severe, and in which an operation did not seem to be indicated. In neither of these cases should opinion be given.

Dr. Chas. W. Oviatt of Oshkosh, Wis., said a case recently came under his observation of a man who was struck in the right iliac region with a board from a circular saw. Rigidity was marked from the start, but other symptoms did not develop for forty-eight hours. The patient refused operation, and died. Autopsy revealed that the cecum was torn loose from its attachment, with a hole in the bowel. No symptoms which would seem to call for immediate operation presented themselves for at least thirty-six hours, and yet this case emphasized the importance of operating early when rigidity was marked.

Foreign Body in the Intestine.—Dr. Charles W. Oviatt of Oshkosh, Wis., reported the following interesting and unique case: A Swede, male, aged 53, was admitted to St. Mary's Hospital, February 22, 1908. It was impossible to obtain anything like a clear history of the patient's previous condition, and no account was given of the swallowing of the foreign body. He complained of pain low down in the right side, and upon physical examination a circumscribed area of resistance could easily be made out with pain on pressure at this point. The pulse and temperature were normal. The diagnosis of appendicitis was perhaps too quickly made, but the author's inability to get a clear history of the case was his excuse. Upon opening the abdomen through the outer border of the right rectus, a pointed foreign substance could easily be felt in the cecum. Through a very short incision into this viscus, a lead pencil, which he showed, seven and a half inches in length, was removed. The appendix was small, presented no evidence of disease and was not removed. On the day following the operation, the patient was shown the pencil and asked if he could account for its presence inside of him. He then remembered that about ten weeks before, while engaged in a game of cards in a saloon, acting in the capacity of scorekeeper, he had the pencil in his mouth and during a fit of laughter swallowed it. He stated that for a day or two following the accident he had some pain in his stomach, but after that had experienced no trouble and had forgotten the incident entirely.

Secondary (Posterior) Gastrojejunostomy Following Recurrent Ulcer at the Site of Anterior Gastrojejunostomy.—Dr. J. F. Percy of Galesburg, Ill., described a case of perforation of a gastrojejunal ulcer following an anterior gastroenterostomy performed eight years previously. The ulcer was on the left side of the union between the jejunum and the stomach. It involved not only the scar tissue of the anastomosis, but also adjacent portions of the stomach and jejunum. The perforation had been sealed by the omentum. He described three things belonging to the intraabdominal picture: First, an enormous thickening of the efferent and afferent loops of the attached jejunum; second, a perforated gastrojejunal ulcer at the point of the previous anastomosis; third, complete burial of the pylorus and adjacent liver region in a mass of dense adhesions. The most striking and insistent thing was the hypertrophy of the jejunum. Its walls were fully two and a half inches in diameter. The operation consisted in removing the jejunum from the stomach wall and closing up the openings, including the ulcer. A posterior gastrojejunostomy was then performed with the short loop.

Dr. L. L. McArthur of Chicago was inclined to agree with Percy as to the influence which an abnormal flow of bile might have in the maintenance of hyperacidity. The bile was naturally the antidote of the acid secretions, and irritation about the gall-bladder would not infrequently influence the condition of the stomach secretions. The theory advanced by Dr. Percy might be further elucidated by laboratory experiments, and he would like to suggest that he have them carried out.

Dr. Chas. H. Mayo of Rochester, Minn., stated that this paper brought to his mind one thing, and that was, that years ago, when there were comparatively few gastroenterostomies done, surgeons heard more about ulcers of the jejunum in proportion than they did to-day.

Diffuse Septic Peritonitis.—Dr. Byron B. Davis of Omaha, Neb., said the decrease in mortality of acute spreading infection of the peritoneum was due to the recognition of three important factors: (1) The chief absorption from the peritoneum was carried on by the diaphragm, seconded by the great omentum; (2) the Fowler position with free tubular drainage from Douglas' cul-de-sac had proven efficient in turning the current in the opposite direction, thus removing the toxines harmlessly; (3) the use of saline solution. As the transition from the older methods to those of the present was slower with some of them than with others, he could only include in his series of cases those operated upon since January, 1907. After the exclusion of cases which could not rightly come in the category of the cases under discussion, his records showed that since January, 1907, he had operated on thirty-nine cases of diffuse septic peritonitis, with three deaths. Thirty-five were due to appedicitis, with one death; two were caused by the perforation of a typhoid ulcer, with one death; one was a case due to puerperal sepsis, with an immense amount of free pus in the peritoneal cavity. This woman recovered. And there was one case of perforating duodenal ulcer which ended fatally. Twenty-eight were males and eleven were females. The average age of all the cases was 26 years and 10 months. The youngest patient was a little boy, aged 5 years, and the oldest was a woman, aged 48 years, the only fatal case due to appendicitis. The appendix was removed at the primary operation in thirty-two cases. In the remaining three the condition was so serious that it was not thought prudent to do more than simple drainage, and the appendix was left. Two of them had had their appendices removed by a subsequent operation. The third one recovered and was still carrying his appendix, but intended entering the hospital to have it removed this winter. In four cases fecal fistulæ persisted, which were cured by subsequent operation. There had been two cases of ventral hernia operated on, and he knew of two others with hernia which would be operated on, if troublesome. There were probably others, as he believed ventral hernia was frequent after such prolonged drainage. There had been no case of intestinal obstruction following these operations. The period of convalescence had in a few cases extended over a number of weeks, and in two of them four and five months respectively. In the greater number the convalescence had been comparatively brief, not longer than he expected after opening an appendiceal abscess.

(To be continued.)

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-second Annual Meeting, Held at Hot Springs, Va., December 14, 15, and 16, 1909.

The President, Dr. Stuart McGuire of Richmond, Va., in the Chair.

(*Concluded from page 171.*)

President's Address: Latent and Active Neurasthenia in Its Relation to Surgery.—Dr. Stuart McGuire of Richmond, Va., emphasized the importance of refusing to operate on a neurasthenic patient unless the symptoms could be plainly shown to be due to organic disease, and he impressed the necessity, if an operation was undertaken on a patient with either latent or developed neurasthenia, of protecting the nervous system from physical or psychical shock, not only by a proper preliminary preparation, but by careful and often prolonged post-operative and post-

hospital treatment. If neuroses existed without anatomical disease, an operation would do no good and might result in harm. If neuroses were found coincident with pathological lesions, an operation might prove of great benefit, but in relieving the physical disease care should be taken to avoid increasing the nervous disorder. If neuroses were present, reflex in character and due to remedial causes, an operation might be undertaken with assurance of complete success. In other words, surgeons should divide these cases into three classes: The first to be avoided, the second to be undertaken with caution, and the third to be cheerfully given the relief to which they were entitled. In discussing the management of neurasthenic patients requiring surgical intervention, he divided the subject into the preliminary examination, the preparation for the operation, the post-operative and the post-hospital treatment. He pointed out the necessity of certain patients remaining for some time at the hospital, and taking a modified form of rest cure, and impressed the point by contrasting the conditions of hospital and home life. The surgeon usually attempted to direct the treatment of patients after they returned home by giving them verbal instructions when they left the hospital, and by subsequently corresponding with them, but the end desired could be more effectively and properly secured by referring the patients back to the family physician. With the rapidly increasing amount of surgery and the consequent number of convalescing patients requiring treatment, an educational move ought to be instituted for the study of the many peculiar factors involved. When surgeons appreciated the influence of neurasthenia on the results of an operation, and the influence of an operation on the production of neurasthenia, when the family physician was educated in the many details of post-hospital treatment and was given legitimate work with proper compensation, then, and not until then, would there be harmony in the profession and the greatest good accomplished to the greatest number of patients.

The Diagnosis of Hyperthyroidism or Exophthalmic Goiter.—Dr. Charles H. Mayo of Rochester, Minn., said that an effort has been made to consider hyperthryoidism a finished product to be diagnosed as such only within the narrow limits of the imperfect descriptions of the few cases described by Parry, Graves, and Basedow nearly a century ago. It was not considered that the thryoid played a more important part than the heart or nervous system. Many marked cases failed in some particular and were classed as *fruste* or pseudo until the lacking symptom appeared. There was a present tendency to drop some of the old classifications and acknowledge that there were various stages; acute, chronic, mild, severe, and irregular forms based upon an increase, probably with some changes of secretion and its delivery. The laboratory findings should show an increase in parenchyma, (a) more cells in the alveoli, (b) more alveoli, (c) papillomatous increase of cells in existing colloid goiter. These changes might be general or in scattered areas. Terminal degeneration of essential organs followed degeneration of the gland in the advanced cases. In this stage the patient might be improved and the disease checked, but not cured by operation. Forms of myxedema were not uncommon in patients who had survived the hyperthyroidism until degeneration destroyed the major portion of the gland. Eye symptoms and heart signs must de differentiated from chronic Bright's disease and from myocardial changes. Leukemia of the neutrophilic polymorphonuclears and the percentage and absolute increase in the lymphocytes should be looked for as diagnostic laboratory aids of some importance. An early diagnosis had become more important since surgery invaded this field than when it was purely medical, in order that a prognosis of the probable result of an operation could be given. In some cases this might mean before eye changes appeared, and in others, before the goiter became a prominent feature.

An Experimental and Clinical Research into Nitrous Oxide and Ether Anesthesia.—Dr. George W. Crile of Cleveland stated that in his service they had given nitrous oxide 575 times for major operations. Among these were included many of the hazardous risks in which ether was contraindicated. Comparing the nitrous oxide cases with ether cases nausea occurred in 17 per cent. as compared with 42 per cent. in ether. This included all cases. Post-operative nausea was, of course, not wholly due to the anesthetic, *i. e.* peritonitis and certain visceral operative trauma might cause nausea independently of the anesthetic. Nausea in nitrous oxide cases in which there was no other nausea-producing factor rarely occurred. In the course of the operation, nausea, in nitrous oxide, as in ether, was usually due to uneven administration. At the conclusion of the operation the patient was fully awake and in unclouded possession of all his faculties in two or three minutes. There was unmistakably a great diminution in surgical shock. Indeed the immunity from shock was as striking in the clinic as in the laboratory. Nitrous oxide as compared with other general anesthetics was technically difficult and expensive. It had certain dangers which were almost wholly in the control of the skilled anesthetist; it was not the anesthetic of choice for the uninitiated, but only for the highly trained anesthetist. Properly supplemented and skillfully given, it might be used as a routine anesthetic in general surgery. Once the operation was over the patient was strikingly better off than after ether anesthesia. In routine operations the combination of scopolamine and morphine given one and one-half to two hours prior to nitrous oxide anesthesia formed so effective a combination that in over 50 per cent. of his patients the day of operation was robbed of all operative memory, and in the remainder it dulled the edge of both the physical and the mental distress.

Gallstones with Reference to Cancer of the Gall-Bladder.—Dr. Albert Vander Veer of Albany, N. Y., detailed his observations on this subject. Of seventy-seven cases not previously reported, there were nineteen males and fifty-eight females, illustrating the fact that females suffered more than males from gall-bladder complications. The diagnosis before operation of the seventy-seven cases was as follows: Gallstones, 64 cases; cholecystitis, 10 cases, and gallstones and carcinoma, 3 cases. Operation revealed a variety of conditions, al lof which were given in tabular form. A study of the mortality list impressed the author with the statement that had been made by other operators that stones in the common duct of long standing were very difficult to reach, and the percentage of deaths was much greater here than in simple cholecystotomy, where there were no such complications. The mortality in the latter cases was very small. One case of the group illustrated most forcibly that marked cholemia was not always fatal after an operation. The experience of surgeons throughout the world during the past ten years indicated that early diagnosis was of the greatest importance to the affected individual.

Acute Suppurative Peritonitis from a Ruptured Pus Tube.—Dr. J. Wesley Bovée of Washington, D. C., said he collected 56 cases of this character that, with the exception of his case, had been previously published. He considered the condition of tube perforation occurring so suddenly as to not permit Nature an opportunity to create a barrier to the outpouring of an infectious fluid accumulation as very rare. In this opinion he believed he was supported by the small number of recorded cases, and the termination of them. The symptoms were quite similar to those of tubal pregnancy, undergoing rupture

or abortion. The collapse, however, was usually greater in this condition than in tubal abortion, and later the symptoms of peritonitis afforded ample ground for making a correct diagnosis. Of the fifty-six cases included in my table, eighteen patients died without the peritoneal cavity having been opened, and necropsies were relied upon for a diagnosis, except in one of Boldt's cases. In the other thirty-eight cases, all operated upon by having the peritoneal cavity opened, though perhaps only drainage was added to the procedure, fourteen, or 37 per cent. died. In one no result was given, and in the twenty-three remaining successful operations, twenty were done during the first day following rupture. But the mortality rate of the operations done on the first day after rupture, in which the results were reported, was 21 per cent., or five in twenty-four. For those done on the second day its was 100 per cent. (3 in 3); for those done on the third day, 67 per cent. (2 in 3), and for those done after the third day 57 per cent. (4 in 7).

Some Therapeutic Adaptations of Cecostomy and Apendicostomy.—Dr. Charles A. L. Reed of Cincinnati stated that these operations, now being done largely at the instance of medical men as adjuncts to their treatment of certain otherwise intractable cases, were based upon the principle that disease within the colon called for treatment addressed to the colon. The advantages of this method of access embraced (*a*) exemption of the stomach for medication, (*b*) escape from impairment of the general health from deranged digestion incident to medication, and (*c*) relief from the uncertainty of remedies that had been subjected to indefinite and undeterminable chemical reaction in the upper digestive tract. The anatomy of the parts pointed to cecostomy rather than appendicostomy as the operation of choice. Among the conditions for which ostiomatic operations of the cecum were now being successfully employed were: (1) amebic dysentery in which it opened the way to treatment more phenomenally successful than has heretofore been realized in the history of this malady; (2) chronic catarrhal or mucous colitis, usually very intractable but which, as shown by his own cases, were cured by this method more promptly and in larger percentage than by other treatment; (3) chronic constipation depending upon atony and not complicated with enteroptosis was readily brought under control as indicated by his own reports confirmed by those of other surgeons; (4) acute septic peritonitis in which, after the operation, the cecum was opened and utilized to flush the colon—"a hot water bottle on the inside"—followed by saline infusion by the drop method, the "coloclysis" of the author with a record of uniform success in the cases in which he had applied it; (5) defective flora of the colon was remedied by the installation through the cecal tube of bacilli chiefly of the lactic acid series; (6) autointoxication of intestinal origin was successfully treated by repeated flushings of the colon through the cecum, the cases recorded embracing cures by this method in chronic headaches, idiopathic epilepsy, rheumatoid arthritis, and pernicious anemia. The recorded experience of his own and that of other surgeons forced the conclusion that: (1) the establishment of colonic irrigation through the cecum, whether by cecostomy or appendicostomy, was a procedue attended with the minimum of surgical risk; (2) the application of the operation as an adjunct of medical practice was based on the principle of direct treatment of the colon for conditions that were local to the colon; (3) the results so far realized justified the continued use of the operation and the more extended application of the principle that it embodied.

Successful Enucleation of a Meningeal Endothelioma Involving the Motor Cortex.—Dr. Stephen H. Watts of Charlottesville, Va., reported the following case: Mrs. S. K., aged 33, housewife, was admitted to the University of Virginia Hospital, September 27, 1909, complaining of headache, vomiting, and dimness of vision. Her family history and previous history were unimportant. The present illness began two years ago with convulsions which she described as beginning in the right corner of the mouth, passing to the right arm and then to the right leg when she would become unconscious. Had had almost constant severe headache which was worse on the left side of the head. Frequent spells of vomiting. Gradual failure of eye sight. Weakness of right arm and left first noticed three or four months ago. Sight was impaired, but she could count figures held in front of her. Marked choking of both optic discs. There was definite motor aphasia. Partial paralyisis of right side of face and right arm, the muscles of the latter being somewhat atrophied. There was little, if any, sensory disturbance. These symptoms and signs seemed to point to a tumor in the lower portion of the left percentral gyrus. On October 5, 1909, an encapsulated tumor 3 by 4 cm. in diameter which proved on microscopical examination to be a meningeal endothelioma involving the arm and face areas of the left motor cortex was removed. The patient made an excellent recovery from the operation. There was no return of the headache or vomiting and when she was discharged on December 1, 1909, the paralysis of the face and arm had almost entirely cleared up. The most disappointing feature of the case was that the sight improved little, if at all, atrophy followed the choking of the discs. This illustrated the importance of earlier operation in such cases.

Surgical Treatment of Epilepsy.—Dr. W. P. Carr of Washington, D. C. made a further report of results of twenty operations for idiopathic epilepsy of severe type and long standing. Six of the twenty cases might be called cured, having passed three or more years without seizures. All except one of these six had been well for four years or more. One as long as ten years. With one exception, those not cured were benefited in being free from convulsions for from two to seventeen months, or in having them in much lighter form and at greater intervals. One was not improved. He believed that the operation had not been tried in the systematic way since improved technique had made it possible and safe and that his results warranted a further trial by surgeons of experience in brain surgery.

Surgical Shock.—Dr. J. G. Earnest of Atlanta gave a description of three cases illustrating some of the phases of surgical shock. In the first very pronounced and profound shock occurred from what would seem to be a trivial cause, uncomplicated with either drugs or hemorrhage, and seemed to the author to favor the theory of reflex paralysis rather than reflex spasm. The second case was a prolonged fight for life in which the patient was kept alive and finally saved by artificial respiration and electricity. The third case was apparently an illustration of delayed shock.

Skin Sterilization by Tincture of Iodine.—Dr. I. S. Stone of Washington, D. C., in his paper gave several good reasons for the use of a better method of skin sterilization, the chief of which were as follows: 1. To save time. The patient was ready for operation immediately after sleep was induced by the anesthetic. No time was spent in washing, etc., which, to be effective, required at least ten minutes. 2. The patient might be kept warm and dry during the entire seance, including the time of anesthesia and operation. 3. If the incision must be extended or one made in another place, this quick method was most desirable. 4. The operator's hands might be sterilized with iodine, as the stain could be removed by a weak solution of aqua ammonia.

Gastromesenteric Ileus Following Gastroenterostomy.

—Dr. Thomas C. Witherspoon of Butte, Montana, reported a case which taught the lesson, (1) of the uselessness of gastroenterostomy as a means of drainage for a paralyzed stomach; (2) the need of early stomach washing before marked paralysis and dilatation could be detected to relieve tension and possibly to diminish intoxication: (3) if after several washings the stomach continued to dilate, the necessity of making free drainage by means of gastroenterostomy should be considered; (4) the necessity of keeping the stomach and bowel as free from alimentary material during the first week or ten days after operative procedures on the alimentary canal as the patient's general condition would allow. He believed the nitrogenous foods were the most harmful. He had seen a reasonable number of these cases and he believed the majority of gastromesenteric ileus attacks were due to a similar cause, and this case threw light on the entire class. He believed it was reasonably apparent that the attack resulted from a trophic change in the spinal segment which had to do with innervating the stomach. The probability was that injury, operative shock, psychic shock, overfeeding, and other causes which upset normal alimentary function or led to intoxication might bring about this condition. The author suggested that every case of gastromesenteric ileus which resisted stomach washing should be drained by means of a gastrostomy, and that such a drain be maintained until the stomach wall had regained its tone.

Extraperitoneal Drainage After Ureteral Anastomosis.—Dr. John E. Cannady of Charleston, W. Va., discussed the theoretical and practical value of extraperitoneal drainage after wounds of the ureter. Wounds of the ureter closed rapidly, even though there was considerable leaking of urine from the ureter. There was great difficulty in making an anastomosis of the ureter that would not leak. The author reported a case and described the technique followed in making an anastomosis and rendering the wound extraperitoneal. He spoke of the ease with which the wound was walled off by the sigmoid and parietal peritoneum. The success of the technique described was evinced by the easy convalescence of the patient. The technique described obviated the danger arising from either primary or secondary leakage at the point of union.

Dr. Thomas S. Cullen of Baltimore detailed an interesting case of large cystic tumor, developing from the iliopsoas bursa, which contained large free cartilaginous masses, and communicated with the hip-joint.

Dr. Wm. S. Goldsmith of Atlanta described a simple method of excising varicose veins.

Dr. Randolph Winslow of Baltimore discussed some acute abdominal conditions in infants under one year of age. He reported three cases of intussusception in infants; one case of strangulated hernia in an infant three weeks old. He then discussed appendicitis in infancy; congenital hypertrophic stenosis of the pylorus; congenital malformation of the anus and rectum; extensive obliteration or total absence of the rectum; imperforate anus, and cited cases illustrating each condition.

Dr. J. E. Stokes of Salisbury, N. C., detailed the symptoms and ultimate treatment of hydatidiform degeneration of the chorion, and reported an instructive and interesting case.

The following papers were also read: "Skin Grafting," by Dr. Arthur C. Scott, Temple, Tex.; "Recent Observations on Surgery of the Pancreas," by Dr. Joseph C. Bloodgood, Baltimore, Md.; "Anatomic Pathologic and Clinical Studies of Lesions Involving the Appendix and Right Ureter, with Special Reference to Diagnosis and Operative Treatment," by Drs. John Young Brown and Wm. Engelbach, St. Louis, Mo.

Officers.—The following officers weer elected for the ensuing year: *President,* Dr. W. O. Roberts of Louisville; *Vice-Presidents,* Drs. Joseph C. Bloodgood of Baltimore and Lewis C. Morris of Birmingham, Ala.; *Treasurer,* Dr. Wm. S. Goldsmith of Atlanta; *Secretary,* Dr. William D. Haggard of Nashville, Tenn. Nashville was selected as the place for holding the next annual meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 7, 1910.

Dr. Charles N. Dowd in the Chair.

A Case of Noma, Followed by Cicatricial Contraction of Jaws.—Dr. William C. Lusk presented this patient. (See page 268.)

Two Cases of Multiple Operations on the Kidney.—Dr. Martin W. Ware said that, after reading the title of the paper which was to follow on "Errors of Diagnosis in Surgical Lesions of the Kidney," he thought it might be well to present these cases to show the pitfalls and errors they were exposed to in trying to meet the indications and relieve these cases.

Case I. This patient was admitted to the genito-urinary department of Mt. Sinai Hospital last August. He could not pass his water and the question arose, Did he have any to pass? The house surgeon said he had none to pass. None flowed through the catheter that was introduced. The man also stated that he had not passed his water for four days, and that during June he had had a similar experience, not passing any urine for three days. The attack passed off. He was forty-two years of age and without family. About nineteen years ago or longer he contracted gonorrhea, following which he was never free from cloudy urine. Nothing was thought of the condition of the kidney, although one doctor said he had stone in the kidney. After entering the hospital he was kept under observation for twenty-four hours, in order, if possible, to determine just what the actual state of affairs was. At the end of this time the anuria had existed five days. He was then cystoscoped and from the mouth of the right ureter was seen to flow an inspissated material like a tooth paste. On the left side nothing was noted to escape. It was surprising to find a man with an anuria lasting five days, yet with absolutely a normal condition so far as temperature and pulse were concerned. His general condition was that of well-being. His tongue was moist. The *x*-ray examination was unsatisfactory. A mass was found occupying the right hypochondriac region. The patient was again examined with the cystoscope and catheterized; the catheters entered either side with great ease; nothing escaped from either ureter. The anuria had now existed for six days. A boric acid solution that was injected returned tinted with a putrid material; this came from the right side, and nothing came from the left catheter. When 6 c.c. of the fluid was thrown into the right side the patient complained of pain and it was thought that there existed a renal colic of the left side. It was finally elected to operate upon the side where the tumor was felt, the right side. The anuria of the left side it was thought might have been due to a reflex condition. Under cocaine the right side was entered and a large kidney found from which pus and stones were removed. The catheter was left in the left kidney and the patient returned to his bed. It was three hours before any appreciable amount of urine was noticed. During the following twenty-four hours three or four ounces of urine were collected. Some purulent urine appeared to be discharging through the nephrotomy wound. The urine coming through the catheter was surprisingly clear. The urine soon began to be secreted in enormous quantities. The *x*-ray taken later

showed two shadows; one was a stone situated near the junction of the ureter with the pelvis of the left kidney. After all it was found that an obstruction existed upon the side not operated upon. Whereupon a ureterotomy was also done under cocaine and the stone removed from the ureter was exhibited. Later the patient was again subjected to an operation; the right kidney was removed and it was found to contain many stones. The pathologist reported this kidney to be also the seat of tuberculosis. The very large kidney was removed piecemeal. The treatment of the stump was very difficult.

Case II. This patient appeared in the spring of 1908 after repeated attacks of renal colic and without other symptoms except painful urination. Following this the urine become cloudy and he had chills and fever. Through the right ureter was found issuing a little urine, but it was impossible to appreciate anything coming from the left ureter. The *x*-ray showed a calculus in the lower end of the left ureter. The urine was very turbid. The calculus, which was situated intramurally, was removed by way of the bladder and the patient made a nice recovery. But the urine did not clear. The *x*-ray showed vague shadows at the time on the opposite kidney. The urine remained turbid. This continued for over a year. At the present time the *x*-ray again showed aforesaid shadows that looked like finger mark prints in the kidney region. There was appreciable swelling in the region of the right kidney just below the border of the ribs. A nephrectomy was done for a huge kidney filled with stones and the patient made an uneventful recovery.

Appendicostomy for Amebic Dysentery.—Dr. Frank Clark Yeomans presented a boy, 13 years old, who was admitted to the New York Polyclinic Hospital, June, 1909, suffering from amebic dysentery. The diagnosis was made by an examination of the stools. On June 29 an appendicostomy was done. There were found only a few adhesions about the appendix. He weighed at the time of operation 82 pounds; he now weighed 94 pounds, and he had gained three or four inches in height. Two or three months ago his irrigations were stopped. No more amebæ were found, although recently some mucus was found at times. The opening in the appendix was left open so that the irrigations could be given again if indicated. The chief sequellæ of appendicostomy were infection of the wound, resulting in hernia and leakage of feces. There had occurred no hernia and no leakage in this case, and the patient was shown to illustrate the end result of an ideal appendicostomy. Prior to the operation the boy was practically an invalid.

Carcinoma of the Ascending Colon. Excision.—Dr. Aspinwell Judd presented a patient, 16 years of age, who had been admitted to the Post-Graduate Hospital October 13. He came in with the diagnosis of appendicitis. Examination revealed a mass about the size and shape of a kidney, but as the kidney could apparently be percussed and palpated it was decided that it was a colon tumor. Upon going down upon it he found that this mass involved almost the entire ascending colon, almost to the hepatic flexure. The retroperitoneal glands were involved. The peritoneum was split on the outer side of the tumor and a section of the growth was sent for a frozen section and microscopical examination. The pathologist reported that the growth was an epithelioma. Dr. Judd then exsected the entire head of the colon, removing about four inches of the small intestine. The anastomosis was made by means of the Murphy button, as a lateral anastomosis was found impossible. He could not get the hepatic flexure down because of the adhesions. This was the fourth case of this nature that he had had and two of them he had presented before the section a year ago. In all the cases he took four or five inches of the ileum away as well. He tied off the blood-vessels as did Dr. Brewer: that is, they were tied close to the colon and he had no difficulty whatsoever. By stripping the layer of peritoneum from the outer side he was enabled to get hold of the mass and glands very satisfactorily. An uneventful recovery followed. Since the operation the patient had gained fifteen pounds in weight. This woman had symptoms of a chronic intestinal obstruction: the lumen of the gut was almost obliterated. The chief interest in the case was that a young girl, only 16 years old, should have such a carcinomatous condition. The Murphy button was passed fifteen days after the operation.

Errors in Diagnosis in Surgical Lesions of the Kidney.—Dr. Alexander B. Johnson read this paper. (To be published later.)

Cystoscopic Findings in Tuberculosis of the Kidney.—Dr. Benjamin Stockwell Barringer gave a lantern slide exhibition of these findings.

An Epidemic of Noma.—Dr. Harold Neuhoff reported an epidemic of noma that occurred in the New York Hebrew Infant Asylum in the spring of 1909. This institution accommodated 150 children. During the epidemic there were 140 children in the asylum under the age of six years. Three cases of noma occurred in the asylum during fourteen years, one in 1902, one in 1907, and one in 1908. All three patients died. The epidemic of noma of 1909 complicated an epidemic of measles. Although special attention was paid to the mouth, ulcerative stomatitis occurred in fully 25 per cent. of the children, and it was among these children that most of the cases of noma developed. There were eight cases of true noma and three doubtful cases. The association of noma with the infectious diseases, especially measles and pertussis, was well known, and the pronounced tendency for noma to appear in the spring and fall might depend upon the greater frequency of the infectious diseases in these seasons. There was no conclusive proof that noma was contagious. The majority of recent observers found no evidence of contagiousness in the epidemics they had studied. With an exposure favorable for the spread of contagious disease, only a few of the patients were attacked by noma and no connection could be demonstrated between the isolated cases. Noma might appear at any age and among all classes of patients. The large majority of the cases occurred among the poorly nourished children, during the first and second dentition, and many developed from ulcers around the teeth. Inasmuch as noma so often followed ulcerative stomatitis, many writers considered noma an advanced stage of stomatitis. It was shown, however, that a definite bacteriological picture was found in noma and not in ulcerative stomatitis. There were usually no constitutional symptoms until gangrene had begun to spread. The child was usually quiet and languid, but he might be restless and irritable. Often he was profoundly prostrated, but he might feel well enough to sit up in bed and play, although the gangrene was spreading over his face. Marked pallor was an early symptom. The pulse soon became rapid and small; there was slight or no temperature and generally no pain. Thirst was marked, although the tongue was moist. Diarrhea was a serious symptom. Bronchopneumonia was the most frequent and fatal complication. It was of the aspiration type and not infrequently led to abscess or gangrene of the lung. The ulcer was usually the first lesion observed, and this soon became gangrenous; the adjoining portion of the cheek became intensely infil-

trated and the gangrene extended to it and often to the adjacent maxilla. The peculiarly penetrating foul odor from the mouth might be the first sign to call attention to the disease. As the overlying skin became involved it assumed a violaceous hue, later turned black and was covered with vesicles; finally the gangrenous ulcer broke through. The mortality ranged from 70 to 100 per cent. Many different kinds of treatment had been recommended. Some men advised applications of alcohol, or hydrogen peroxide, or potassium chromate, nitric acid, etc. Others advised cauterization of the ulcer, and others practised excision of the diseased area. Dr. Neuhof offered the following conclusions: Noma usually appeared in epidemic form; its contagiousness had not yet been proven. The disease was an entity and not a later stage of ulcerative stomatitis; the latter offered a good soil for the development of noma. There was regularly present in noma a streptothrix characterized by a thick mesh-work of mycelium at the border line between the normal and necrotic tissue; fine rods and spirilla extended from the mycellum into the adjacent tissues. The constant presence of the streptothrix, to the exclusion of other bacteria, indicated that in all probability it stood in etiological relationship to noma. The streptothrix was present in noma before the disease was fully manifested, in the pregangrenous stage. It was in this stage of the disease that radical treatment has to be practised; after the ulcer had spread the best results were obtained by conservative measures. General anesthesia should not be employed in any form of treatment because of the pronounced tendency to the development of septic pulmonary disease.

Dr. Arthur D. Dryfoos said that the streptothrix described by Perthes in 1893 had been previously described by Babes in 1892. Ranke, also Seifert, Blumer, and MacFarlane, had isolated the same organism, but Babes did not regard it as being specific. The general consensus of opinion, according to Wassermann and Kolle, was that under certain unknown favorable conditions various bacteria could cause noma. This probably explained the fact that Walsch and others regarded noma as diphtheritic. The cases shown were certainly not of this category, as several received large doses of antitoxin without any apparent benefit. One of the patients had primarily a diphtheria of the vulva. This cleared up promptly under a very large dose of antitoxin, but shortly afterwards developed an ulceromembranous stomatitis. Noma, ulceromembranous stomatitis, and Vincent's angina were regarded by Rona and most observers as being merely different stages and localizations of the same disease. Noma was invariably preceded by ulceromembranous stomatitis; but on the other hand every case of ulcerative stomatitis, even if it was attended by a certain amount of localized necrosis of bone and superficial ulceration of the mucous membrane, was not noma. Dr. Neuhoff's cases seemed to have been a rather severe form of ulceromembranous stomatitis, but could not be properly classed as noma. There was a third type of mouth infection which he also had the opportunity of seeing during this epidemic. They were cases of so-called Vincent's angina. These cases gave a great deal of trouble, as diphtheria was also prevalent and it was impossible to differentiate the membranes. Babes had also described a bacillus, which he found in an epidemic of scurvy, and which was either identical with Vincent's bacillus or was a variety of the same. He said that most observers agreed that these bacilli (Perthe's, Vincent's, etc.) could also occur normally in the mouth, and that they proliferated and produced enormous destruction of tissues under favorable conditions, not as yet determined. Israel and Partsch ascribed a great rôle to carrous teeth in the production of ulceromembranous stomatitis. Dr. Dryfoos thought that these authors had confused cause and effect. It was well known to dentists that caries of the teeth was often associated with an acid saliva. Mosler ascribed the caries of the teeth occurring in diabetes to the action of acid saliva, which was produced by lactic acid fermentation. This was certainly true only in part. Wright had demonstrated experimentally that there was a reciprocal relation between the acidity of the gastric juice and the reaction of the saliva; it was very probable, therefore, that contagious diseases, such as measles and diphtheria, were associated with subacidity of the gastric juice and marked acidity of saliva. This altered reaction of the saliva was, he believed, the factor which favored the development and heightened the virulence of these mouth bacteria. It was very interesting to note that Bierens de Haan, reporting an epidemic of ulceromembranous stomatitis among the Boer troops, said "that the epidemic was largely due to a lack of salt in the diet, inasmuch as it began to disappear as soon as a proper supply of this substance was obtained." Litten in a monograph on scurvy expressed a similar view; he said "that scurvy may be looked upon as an infectious disease of non-contagious character, caused by a microorganism which finds suitable conditions for development in a soil poor in potassium salts." It was possible that scurvy represented merely a hemorrhagic form of mouth infection, of which noma was another variety. Noma as such was not contagious, but ulceromembranous stomatitis was readily communicated from one child to another by means of eating utensils. It was to be noted that the epidemic reported by Blumer and MacFarlane, and referred to by Dr. Neuhoff in his paper, ceased as soon as a strict isolation was observed.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, State of Florida.

Jacksonville, November 10 and 11, 1909.

ANATOMY.

1. Describe the clavicle.
2. Name points of interest on the external surface of the occipital bone.
3. Describe the liver.
4. Name regions of abdomen and contents of each.
5. Give description and branches of the largest nerve of the brachial plexus.
6. Give apparent and real origin and exit of facial nerve.
7. Give branches of the axillary artery.
8. Name most important branch of the occipital artery, and state chief function it has to perform upon ligation of the carotid.
9. What forms the torcular herophili?
10. Name veins that compose the portal circulation, with a description of any one of its branches.

PHYSIOLOGY.

1. Give the composition, reaction, and uses of blood.
2. What changes take place in the composition of the blood as it passes through the kidneys?
3. What is respiration, and what is its purpose?
4. Do variations in the rate and force of respiration affect the heart, and if so, in what manner?
5. What is asphyxia, and what are some of its causes?
6. What is gastric juice, and what part does it play in digestion?
7. What gland secretes amylopsin, and what is its action in digestion?
8. What are the principal uses of water when taken into the body?
9. What is metabolism?
10. —Give the functions of the pneumogastric nerve, particularly its action upon the heart.

MATERIA MEDICA—THERAPEUTICS.

1. Mention some of the conditions which affect the dosage of medicines, and give the general rule for calculating doses for children.
2. How are the iodides best administered, and in what class of cases would you prescribe them?
3. Give the dose of salol, indications for its use, and the two drugs it is subdivided into in the stomach.
4. Describe the physical properties and physiological action of heroin. Give some of the indications for its use.
5. Name some of the drugs that are incompatible with calomel, and state why.
6. Give the symptoms of a toxic dose of digitalis and your treatment of such a case.
7. Describe and give the indications for the use of cardiac sedatives, with an example.
8. Why is it best to combine atropine with morphine, and in what doses would you use it?
9. What are the three preparations of opium most used, and how much of each dose does it take to represent one grain of opium?
10. What are antipyretics? By what methods do they act? Name the ones most generally used.

CHEMISTRY.

1. What is the difference between a molecule and an atom?
2. How is the equivalence of atoms expressed, and how termed in notation?
3. What is the result of water being subjected to electrolysis, and how does it take place?
4. What is ethyl hydrate, and how obtained?
5. Give some of the reactions illustrating the incompatibilities of $Hg_2 Cl_2$.
6. Describe Fehling's test for sugar.
7. How is glucose made, and what used for?
8. Give a test for morphine.
9. What are the reactions analytically between mercuric and mercurous chlorides?
10. How would you test for urea?

SURGERY.

1. Define infection, inflammation, suppuration.
2. Define atrophy, hypertrophy.
3. Define hydrocephalus, hydrocele.
4. Define thrombosis, embolism, aneurysm.
5. Describe the healing process in an incised wound. Healing by granulation.
6. How would you treat a case of gangrene?
7. What are the reasons for ligating a blood vessel?
8. What are the contraindications for the use of chloroform, ether?
9. What is a tumor? How are they classified?
10. What is the principle on which the serum treatment of diseases is based?

GYNECOLOGY.

1. Give location, size, shape, and supports of a normal uterus.
2. What is anteflexion? Give its symptoms and treatment.
3. What is retroflexion? Give some of its causes and symptoms.
4. Describe briefly the following conditions:
   (a) Amenorrhea.
   (b) Vicarious menstruation.
   (c) Supplementary menstruation.
   (d) Menorrhagia.
   (e) Metrorrhagia.
5. Define dysmenorrhea and give some of its chief causes.
6. Give tissues lacerated in incomplete laceration of perineum. Same in complete laceration.
7. Mention some of the physical changes that take place during the menopause.
8. Give etiology, symptoms, and trreatment of cancer of cervix.
9. Define cystocele. Rectocele. Give principal causes and symptoms.
10. Describe briefly the operation for radical cure of cystocele.

OBSTETRICS.

1. Give the symptoms of pregnancy prior to the beginning of the fourth month.
2. What are the positive signs of beginning labor?
3. Describe in detail the management of a normal case of labor at term.
4. Under what conditions are the use of forceps justifiable?
5. Describe the manner of application of forceps.
6. What is placenta prævia, how recognized and treated?
7. Describe the postpartum hemorrhage, and give best methods for its treatment.
8. Define eclampsia, and describe its management.
9. What are the dangers incident to breech presentations, and how are such conditions best managed?
10. Describe the best methods of resuscitating a stillborn child.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF FLORIDA.

Jacksonville, November 10 and 11, 1909.

ANATOMY.

1. The *clavicle* forms the anterior part of the shoulder girdle; it articulates internally with the first part of the sternum, and externally with the acromion process of the scapula. It is broad and flattened at its outer end, and thick and rounded at the inner end. It consists of a double curve, the outer part is concave forward, the inner part convex forward. The bone has two surfaces, superior and inferior, and two borders, anterior and posterior. On the under surface are the conoid tubercle, a groove for the subclavius, a rough impression for the rhomboid ligament. *Muscles attached to it* are: Deltoid, trapezius, pectoralis major, subclavius, sternomastoid, and sternohyoid. *Ligaments attached to it* are: Interclavicular, rhomboid, conoid, trapezoid, and capsular (of sternoclavicular and acromioclavicular articulations).
2. External occipital protuberance, external occipital crest, superior, inferior, and highest curved lines, foramen magnum, condyles, basilar process, pharyngeal spine.
3. See Cunningham's "Anatomy" (1909), page 1108; or Gray's "Anatomy" (1907), page 1334.
4. The regions of the abdomen and their contents are shown in the following table. It is to be remembered that the contents will vary according to the position of the lines drawn; these are arbitrary, and nearly every writer differs from every other. In the following table the superior horizontal line extends between the cartilaginous ends of the tenth ribs, the inferior between the anterior superior iliac spines. The vertical lines pass upward from the iliopectineal eminences, at right angles, to the upper horizontal line.

The viscera situated in each region are as follows:

RIGHT HYPOCHONDRIAC	EPIGASTRIC.	LEFT HYPOCHONDRIAC
Liver.	Liver.	Stomach.
Right kidney.	Stomach.	Spleen.
Hepatic flexure of the colon.	Gall-bladder.	Left kidney.
	Duodenum.	Splenic flexure of the colon.
	Pancreas.	
RIGHT LUMBAR	UMBILICAL	LEFT LUMBAR
Right kidney.	Transverse colon.	Small part of left kidney.
Ascending colon.	Duodenum and small intestines.	Descending colon.
Ileum.	Great omentum.	Small intestines.
RIGHT ILIAC	HYPOGASTRIC	LEFT ILIAC
Cecum.	Small intestines.	Sigmoid colon.
Appendix.	Bladder in children.	Small intestines.
Last coil of ileum.	Distended bladder in adults.	
	Pregnant uterus.	
	Sigmoid colon.	

5. Median nerve. See Cunningham's "Anatomy" (1909), page 627; or Gray's "Anatomy" (1907), page 1004.
6. FACIAL NERVE. *Apparent origin:* Medulla oblongata, in groove between olivary and restiform bodies. *Real origin:* Nucleus in floor of fourth ventricle. *Exit:* Through stylomastoid foramen.
7. Superior thoracic, alar thoracic, acromial thoracic, long thoracic, subscapular, anterior circumflex, posterior circumflex.
8. The most important branch of the occipital artery is the arteria princeps cervicis; after ligation of the carotid, it anastomoses with the superficial cervical (of Transversalis colli) and deep cervical (of subclavian or superior intercostal).
9. The torcular herophili is formed by the superior longitudinal, lateral, straight, and occipital sinuses.
10. The gastric, splenic, superior mesenteric, and infe-

rior mesenteric veins make up the portal vein. For description of one of these veins, see Cunningham's "Anatomy" (1909), page 903; or Gray's "Anatomy" (1907), page 768.

PHYSIOLOGY.

1. The *constituents of the blood* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteids, leuconuclein, lecithin, histon, etc.). Its *reaction* is alkaline. Its *functions* are: To carry oxygen from the lungs to the tissues; to carry carbon dioxide from the tissues to the lungs; to convey the absorbed food to the tissues; to protect against bacteria; to carry waste material to skin, lungs, and kidneys for excretion.

2. As it passes through the kidneys the blood loses: water, mineral salts, urea, uric acid, oxygen, and carbon dioxide.

3. Respiration is the act of breathing; it includes both inspiration and expiration. Its purpose is to introduce oxygen into the system and to excrete carbon dioxide.

4. Yes; increased frequency of respirations generally cause increased frequency of heart beats, but not always in the same proportion.

5. Asphyxia is suffocation, due to depriving the lungs of oxygen. It is caused by preventing oxygen from reaching the lungs; by obstruction of the respiratory passages; by inhaling a gas without oxygen, or one which strongly tends to displace oxygen from the hemoglobin, as carbon monoxide; or by interfering with the change of gases which should take place between the air and the blood.

6. Gastric juice is the product secreted by the glands of the stomach. It changes proteids into proteoses and peptones, and coagulates milk.

7. Amylopsin is secreted by the pancreas; it changes starches into sugar.

8. *Uses of water in body:* "It enters into the composition of the tissues; it is the chief ingredient of all the fluids, and maintains their proper degree of dilution; it moistens the various surfaces (mucous and serous membranes), and so prevents friction; it furnishes blood and lymph with a fluid medium by which food may be taken to remote parts of the body and the waste matter removed, thus promoting rapid tissue change; it serves as a distributor of body heat; it regulates the body temperature (by absorption and evaporation)."

9. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) anabolic, or constructive, and (2) catabolic, or destructive. The changes produced in the cells by the oxygen or nutrition conveyed by the blood come under the class of anabolic changes.

10. *Functions of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory*, and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the heart; (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc."—(Kirkes' *Physiology.*)

MATERIA MEDICA—THERAPEUTICS.

1. The conditions which affect the dosage of medicines are: Age, body weight, body temperature, drug habits, idiosyncrasy, method of administration, intervals between doses, cumulative action of drug, disease, and race.

Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

2. The iodides are best administered in a syrup, such as the compound syrup of sarsaparilla; and no other drug should be administered at the same time. Iodides are prescribed in: Syphilis, chronic rheumatism, for absorption of inflammatory products, arteriosclerosis, interstitial nephritis, asthma, goiter, skin diseases, lead and mercury poisoning.

3. SALOL. *Dose:* gr. vijss. *Indications for use:* As a disinfectant, in inflammations of mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera. In the stomach it is subdivided into salicylic acid and carbolic acid.

4. *Heroin* is a fine white powder, insoluble in water, soluble in dilute acids. It is a respiratory sedative, but has very little hypnotic or analgesic effect. It is used for coughs and bronchitis.

5. *Incompatibilities of calomel, with reasons:* Solutions of alkalies and their carbonates convert calomel into a black mass, usually the black oxide; ammonium hydroxide and carbonate form with it a complex black compound; iodides, bromides, cyanides, and other reducing agents convert it into mercury and a mercuric compound; oxidizing agents oxidize it to the mercuric state; exposure to sunlight gradually decomposes calomel; this is accelerated by the presence of iodoform and other organic substances."

6. *Symptoms of poisoning by digitalis:* "Nausea, and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours, marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient. Death is generally by syncope, sometimes after several hours of coma succeeded by convulsions. *Treatment:* The patient must be kept strictly in the recumbent position. The stomach should be washed out with infusion of tea by the stomach tube. Stimulants should be given."—(Witthaus's *Essentials of Chemistry.*)

7. *Cardiac sedatives* are drugs which lessen the force and frequency of the heart's action. They are used to quiet palpitation of the heart, also to slow the pulse in some fevers. Aconite, antimony, potassium, chloral, digitalis are cardiac sedatives.

8. Atropine is often combined with morphine when the latter is used, for the following reasons: (1) To prevent nausea and insomnia; (2) to intensify the effect of the morphine, and so a smaller dose may suffice; (3) to neutralize the effect on the pupils. The dose of morphine could be gr. ⅛ to ¼; of atropine, gr. 1/150 to 1/100.

9. (1) Tincture of opium; ten minims = one grain of opium. (2) Camphorated tincture of opium; half ounce = one grain of opium. (3) Dover's powder; ten grains = one grain of opium.

10. The following table (from Potter's "Materia Medica") gives the chief temperature depressants, with their manner of action: Temperature depression may be done by five different actions working upon two principal lines, viz., by:

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change.
- (2) reducing the circulation.

(*b*) *Promoting heat loss, by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration—its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Alcohol, 1, 3.
Phenol, 1.	Nitrous ether, 3, 4.	Antimony, 2, 4.
Salicin, 1.	Acetanilid, 1, 4.	Cold bath, 5.
Digitalis, 2.	Phenacetin, 1, 4.	Cold drinks, 5.
	Antipyrin, 1, 4.	Wet pack, 5.

CHEMISTRY.

1. An *atom* is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule. A *molecule* is the smallest quantity of any substance that can exist free. It is made up of atoms.

2. The equivalence of atoms is expressed in terms showing ratio with that of hydrogen: univalent, bivalent, trivalent, quadrivalent, quinquivalent, etc.

3. The water is split up into hydrogen and oxygen gases which can be collected.

4. Ethyl hydrate is alcohol. C_2H_5OH. It is made by alcoholic fermentation of grape sugar:

$$C_6H_{12}O_6 = 2CO_2 + 2C_2H_5OH$$

grape sugar — ethyl hydrate

5. $Hg_2Cl_2 + Ca(OH)_2 = CaCl_2 + H_2O + Hg_2O$.

And see MATERIA MEDICA, question 5, and CHEMISTRY, question 9.

6. *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out. [The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use, equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

7. Glucose may be made by heating cane sugar with dilute sulphuric acid. It is used as a sweetening agent, and as a vehicle for medicines.

8. Solution of neutral ferric chloride gives a blue color with morphine.

9.

MERCUROUS.	MERCURIC.
H_2S a black ppt., insol. in NH_4HS, HCl, or HNO_3.	ppt. at first white, then orange, then black.
NH_4HS a black ppt., insol. in excess.	ppt. white to black, insol. in excess, except in presence of organic matter.
$(NH_4)_2CO_3$ a dark gray ppt., sol. in hot HNO_3, insol. in H_2SO_4.	white ppt., sol. in great excess of reagent, in H_2SO_4, or in NH_4HO.
KHO a dark gray ppt., insol. in excess.	yellowish-red ppt.
NH_4HO same as KHO.	white ppt., slightly sol. in excess, strong acids, or NH_4Cl.
KI a greenish ppt.	yellow to salmon to red ppt., easily sol. in excess of KI.

10. To a small amount of the suspected fluid add equal amount of colorless nitric acid; if urea is present crystals of urea nitrate will quickly appear.

SURGERY.

1. *Infection* is a process due to the access of living, virulent, pathogenic bacteria to a part whence their toxins may act on the tissues of the body.

Inflammation is the succession of changes occurring in a part as the result of an injury which is not sufficient to destroy the part.

Suppuration is the process when inflammation is followed by liquefaction of the tissues; it is due to the presence of pyogenic bacteria.

2. *Atrophy* is decrease in the amount of a tissue owing to diminution in size or number of the histological elements of which it is composed.

Hypertrophy is an increase in the size, weight and functional activity of a part beyond the limit of health, and due to an orderly enlargement or multiplication of all its normal constituents.

3. *Hydrocephalus* is a condition characterized by excess of fluid in the ventricles of the brain, or outside the ventricles but within the cranium.

Hydrocele is a collection of fluid other than pus or blood in the neighborhood of the testis or spermatic cord, generally in the tunica vaginalis of the testis.

4. *Thrombosis* is the coagulation of blood within the vessels during life.

Embolism is the inpaction of solid substances circulating in the blood in vessels which are too small to allow them to pass.

Aneurysm is a cavity containing blood, and communicating with the lumen of an artery.

5. Healing in an incised wound, if aseptic, and the edges are in apposition, occurs by *first intention.* "Exudation of plasma from the neighboring blood-vessels occurs, and its fibrinogen is converted into fibrin, so gluing the edges of the wound together. Leucocytes are poured out and infiltrate the wound, absorbing any blood clot present. These are followed by fibroblasts (connective-tissue cells), which take their place. New capillaries form by budding out from adjacent ones, and vascularize the new tissue. Fibrous tissue is formed by intercellular exudation from the fibroblasts and so the fibrocicatrical union is complete, for at the same time epithelium is spreading over the narrow surface line."

Healing by granulation or second intention occurs when the edges of the wound have not been brought together. "Exudation of plasma and leucocytes occurs, followed by fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibrocicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in from the edge over the surface, and so the scar is completed."—*Aids to Surgery.*

6. See Rose and Carless' Surgery (1908), pages 102, 104, 106, 107, 109, 110, 112, 114, 115, and 117; or Da Costa's Surgery (1908), pages 170, 172, 174, 176, 177, 178, 180, and 183.

7. *Reasons for ligating a blood vessel:* To stop hemorrhage, to cure aneurysm, to starve a tumor, and as a preliminary to some bloody operations.

8. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

9. A *tumor* is a pathological new growth which tends to persist independently of the structures in which it lies, and which performs no physiological function.

Tumors are classified as follows:—

I. Those derived from mesoblast:
   (*a*) *Benign:* Lipoma, fibroma, chondroma, osteoma, myxoma, myoma, neuroma, glioma, angioma, lymphangioma.
   (*b*) *Malignant:* Sarcoma.

II. Those derived from epiblast or hypoblast:
   (*a*) *Benign:* Adenoma, papilloma.
   (*b*) *Malignant:* Carcinoma.

III. Cystic tumors.

IV. Teratomata.

10. "*Serum therapy* proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood serum containing an antibody which is specific to the particular disease." (Potter's *Materia Medica.*) *Examples:* (1) Diphtheria antitoxin; (2) antitetanic serum; (3) antivenomous serum.

GYNECOLOGY.

1. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity, and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

2. *Anteflexion* is an anterior displacement of the uterus, in which the uterus is bent upon itself. *Symptoms:* Dysmenorrhea, sterility, and various reflex nervous phenomena (such as disturbances of the bladder). *Treatment:* Dilatation of the cervical canal or a plastic operation (division of the cervix).

3. *Retroflexion* is a posterior displacement of the uterus, in which the uterus is bent upon itself. *Causes:* Distended bladder, retrouterine peritonitis; chronic cystitis; small fibroid in posterior wall of uterus; too long a period in the recumbent position after labor, or too tight bandaging; tight lacing; infection during puerperium; pressure of tumors; inflammations of uterus and its appendages; gonorrhea. *Symptoms:* Bladder disturbances; constipation and painful defecation; dysmenorrhea, or amenorrhea, or hemorrhages from the uterus; leucorrhea; sterility, or frequent abortion.

4. (*a*) *Amenorrhea* is absence of menstruation during

the period of sexual activity. (*b*) *Vicarious menstruation* is a flow of blood from some organ (other than the uterus) recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the mammary glands, ulcerated surfaces, and many other parts. (*c*) *Supplementary menstruation* means a menstrual flow from the uterus and also from some site (as given under vicarious menstruation. (*d*) *Menorrhagia* is a condition characterized by excessive loss of blood during the menstrual periods. (*e*) *Metrorrhagia* is a hemorrhage from the uterus at other than the menstrual periods.

5. *Dysmenorrhea* is painful menstruation. *Chief Causes:* Pelvic congestion, pelvic inflammationfi malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of uterus.

6. In *incomplete laceration of the perineum* any of the following tissues may be lacerated: Skin, mucous membrane of fourchette, Constrictor vaginæ, Transversus perinei, and Levator ani. In *complete laceration* the sphincter ani and the anterior surface of the rectum are involved, in addition to the structures named above.

7. *During the menopause:* Menstruation first becomes irregular both in periodicity and quantity, and then ceases; the patient suffers from hot flashes, giddiness, pains in breasts, abdomen or limbs; indigestion, flatulence, constipation and obesity may be present. The ovaries become smaller and wrinkled, the vagina becomes smaller, the cervix atrophies, the body of the uterus diminishes in size, the pubic hair becomes less, and is shed, the external genitals atrophy.

8. *Cancer of cervix:* "Laceration and erosion are predisposing factors. It occurs most frequently between the ages of 35 and 50. The symptoms are hemorrhage, pain, and discharge. The diagnosis is made on the physical and microscopical examination. The cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. These nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable and bleeds upon touch. The prognosis is unfavorable unless a radical operation is performed. The treatment consists in removal of the entire uterus, but is contraindicated when the disease has extended to inaccessible organs. The palliative treatment consists in relieving the pain by morphine and in the removal of the diseased tissue by the scissors, curet, or caustic for the relief of the hemorrhage and discharge."

9. *Cystocele* is a hernia of part of the bladder into the vagina, covered by the mucous membrane of the anterior vaginal wall. *Rectocele* is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall. The two conditions are generally found together. *Causes:* Lacerated perineum, prolapsed uterus, relaxation of the structures forming the pelvic floor, and subinvolution of the vagina after labor. *Symptoms:* A dragging sensation in the lower pelvic cavity; a feeling of distention at the vulva; loss of power in urination or defecation; tumor of anterior or posterior vaginal wall (or both) more apparent on straining; prolapse of uterus.

10. *For radical cure of cystocele:* "The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant, and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps —one at each of the sidemarks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromieized catgut is passed under the whole pared surface, uniting the edges from side to side." If necessary, a perineorraphy should be done at the same time.

OBSTETRICS.

1. Cessation of menstruation, changes in the breasts, morning sickness, pigmentation, increased frequency of urination, the cervix is soft; none of these are definite or conclusive.

2. The uterus sinks, the bowel and bladder evacuations are more frequent, free vaginal secretion, a slight discharge of blood or bloody mucus, dilatation of the os, and characteristic rhythmic uterine pains.

3. See Williams' "Obstetrics" (1909), page 303; or Hirst's "Obstetrics" (1909), page 312.

4. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (a) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapse funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

5. See Williams' "Obstretrics" (1909), page 403; or Hirst's "Obstetrics" (1909), page 811.

6. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

7. See Williams' "Obstetrics" (1909), page 818; or Hirst's "Obstetrics" (1909), page 585.

8. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Control the convulsions (by chloroform, veratrum, or chloral); (2) eliminate the poison or poisons which are presumed to cause the convulsions; (3) empty the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

9. See Williams' "Obstetrics" (1909), page 289; or Hirst's "Obstetrics" (1909), page 424.

10. See Williams' "Obstetrics" (1909), page 846; or Hirst's "Obstetrics" (1909), page 939.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	W. H. Sanders, Montgomery	Montgomery.... June —
Arizona*	Ancil Martin, Phoenix	Phoenix..... April 4
Arkansas	F. T. Murphy, Brinkley	Little Rock..... May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco.. April 5
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver..... April 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven .... Mar. 8

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of February 5, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	650	184
Diphtheria	397	42
Measles	1,095	17
Scarlet Fever	635	26
Smallpox	—	—
Varicella	146	—
Typhoid Fever	19	4
Whooping Cough	31	3
Cerebrospinal Meningitis	3	10
Malarial Fever	—	—
Totals	2,976	286

Nasal Perforations Due to Salt.—McKenzie reports an examination of eight persons working as packers of table salt. Four of them showed perforations of the nasal septum. In other respects they were unusually healthy. There was no history of syphilitic infection or signs of the disease. Legge reported 126 cases of septal perforation among 176 men employed in the manufacture of bichromates.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 4, 1910:

THE THALAMIC SYNDROME.

BY SMITH ELY JELLIFFE, M.D., PH.D.,

NEW YORK.

ATTENDING NEUROLOGIST, CITY HOSPITAL, NEW YORK; ASSISTANT NEW YORK NEUROLOGICAL INSTITUTE; CLINICAL PROFESSOR OF PSYCHIATRY, FORDHAM UNIVERSITY.

THE description of the thalamic syndrome, first conceived by Déjerine in 1903[3]; made more precise, and apparently named for the first time by him and Thomas before the February 4, 1904, séance of the Paris Neurological Society,[4] and finally elaborated by Déjerine and Roussy[9] in 1906 on the basis of the histological examination of the first case of Déjerine and Egger, and by Roussy in his Interne Thesis,[11] is one of the most striking of the recent contributions to clinical neurology and to the anatomy and physiology of the sensory components of the central nervous system. Some eighteen to twenty cases of this syndrome have been reported, of which four are by Coriat, of the United States. A critical analysis will undoubtedly reduce the number somewhat.

Through the courtesy of Dr. E. C. Fassett, of this city, I am enabled to record the case history of a patient who exhibited the syndrome as a part possibly of a progressive disorder the exact diagnosis of which is still a matter of uncertainty.

CASE. November 3, 1909. W. P. S., aged 40, single, real estate. A man of considerable activity and force. Hereditary history is negative; his parents were not related, and there is no history of nervous or mental disease in the ascendants. Epilepsy, alcoholism, suicide, diabetes, and syphilis are absent from the family history.

His was a normal birth, and he learned to walk, speak, and read normally; did not suffer from teething cramps, nor rachitis, and had no severe children's disorders; no childish bladder difficulties. School normal—well educated man; nonalcoholic. Of later diseases, chancre 13 years previous. Was treated by Dr. E. L. Keyes for two years. One year later he reports having had a loss of power in the left arm of about four weeks' duration, the nature of which is obscure. Since that time he has been well, save for the past couple of years, when he noticed he grew tired readily, and that his work, which requires a very intense kind of effort, exhausted him.

In August, 1908, he was found unconscious in his bathroom at 5 P. M. The next day his temperature was 101° F., respiration 35, pulse 36. His pupils were small and irregular, the right larger than the left. According to the nurse, he had vomited and had had some convulsions. He showed exaggerated reflexes and was semi-conscious for two days. There was no loss of sphincter control. He was amnesic from the afternoon of the day he was taken, remembering only that he felt a little dizzy. He recovered without any paralysis. He spoke at first a little thickly, and jumbled his words. He had no difficulty in walking. There were no sensory defects.

The history of this attack, which lasted a few weeks, is somewhat fragmentary, but is suggestive of a paretic attack. He was placed upon mixed treatment and made a rapid recovery. He went to business in May, June, and July, but his head bothered him a great deal—it felt thick.

He came under Dr. Fassett's care in March, 1909, suffering from a severe vertiginous headache which was controllable by potassium iodide and ergot. On the morning of October 10, 1909, when the patient woke he was sick, vomited, and noticed that he was weak in the right side of the body, his arm and leg commenced to get heavy; he was unable to walk, save with help, and he could not govern the movements of his right hand. The afternoon before he had had an unpleasant feeling in his head, with dizziness. The symptoms were suggestive of a functional hemiparesis and hemianesthesia at that time.

Examination, November 3, 1909.—Patient is well-built man, muscular, compact and stocky, not large, with abundant fatty deposit, and good state of nutrition. His general organs are all healthy. Skull not painful on percussion.

Cranial Nerves.—I. Smell: r = 1; symmetrical; asafetida and oil of turpentine, as tests.

II. Sight: r = 1; 20/20; no hemianopsia; no color changes; no limitation of visual fields, fundus normal.

III, IV, VI. Eye movements free and ample in all directions; no nystagmus; no double vision; slight tendency to ptosis of right eyelid while face is at rest. Pupillary reactions: to light slightly sluggish; pupils, irregular, small, the left is more dilated than the right; to accommodation prompt and ample, the two are equal.

V. Trigeminal sensory area negative; motor power; masseters normal; corneal, palpebral, and conjunctival reflexes, present, r = 1 symmetrical. Supraorbital and infraorbital and mental points are negative. Occasional twitches of pain in the right side of the face, but nothing severe.

VII. Motor functions, r = 1, symmetrical; slight tendency to flattening of right nasolabial fold at rest; nares equal and symmetrical; all movements of the facial muscles, wrinkling of forehead, closure of eyes, whistling, puffing cheeks, equal and symmetrical; emotional movements equal and symmetrical; speech short and jerky; test phrases—no stumbling; tongue protruded in middle line; no tremor, atrophy, no scars; slight tic-like movements lips, eyelids, etc.

VIII. Hearing: Watch 1 foot right side; left, 3 feet; no buzzing, nor dizziness; Rinné, positive.

IX, X, XII: Negative; pharyngeal reflexes r = l; symmetrical.

XI: Slight weakness of the muscles of the right shoulder, not marked; turning of neck, slight paresis right side.

Upper Extremities.—Atrophy: Slight flabbiness on right side; left side normal. Hypertrophy: o; r = l. Spasms: o: r = l. Hypotonus: slight, on right side. Muscular force: right side weaker than the left, difference marked in smaller muscles of hand; no paralysis, but distinct paresis; large associated groups performed well; finer movements poor on the right side.

Marked adiadochocinesis, right side, none on the left.

Triceps reflex, + +, right greater than the left, not marked.

Radius periosteal reflex, + +, right greater than the left, not marked.

Tremor: Wrist, at rest, o; static, o; locomotor, ataxic, and irregular choreoathetoid movements slow, twisting and then jerky on right side only, which are made worse when motion is thought of. It is not an intention tremor, but becomes steadier and steadier as motion progresses.

Finger-Nose Test: Coarse irregular, static swaying with marked inability to find nose on right side; left side normal. Excess of motion in right side by finger-nose test and by line test. Finger-finger test same as with preceding.

Sensory Perceptions.—Muscle position sense; right side gone. Patient could not imitate movements, nor place arm or hand in position of left hand. Sense of joint movements flexion, abduction, pronation and apposition lost on right side. Left side normal.

Stereognosis: Right side, patient unable to recognize any objects, nor qualities of objects, whether rough, smooth, square, round, or triangular. The movements of the fingers in palpation are clumsy and irregular.

Light touch (brush) somewhat but not markedly impaired; the patient localizes light touch fairly well over the upper arm, but there is more loss in hand. The diminution is therefore centripetal. The loss is segmental and not radicular. Point and head of pin confused throughout the lower half of the forearm and hand. The distribution segmental and centripetal confusing as to outlines where arm and trunk coincide, growing more definite—errors less on ascending arm and descending the trunk. No sharp line of demarcation. These changes were confined to the right side.

Stern Test: Mistakes constant in forearm and hand, less marked in forearm and trunk. Left side negative. Slight pains in right shoulder; irregular; pains in irregular attacks but not extremely severe, and not requiring special treatment. Heat and cold sense indefinite on the right side. Bone conduction diminished on right side; lost in bones of hand.

Trunk: No paralyses nor atrophies. Patient on back shows no ataxia; no static fixation; no cerebellar catalepsy on back. Dermographia, o; pressure points, o. Abdominal reflexes, +, r =l, symmetrical. Cremasteric, +, r = l, symmetrical. Sensory disturbances not marked. Pain sense somewhat diminished on right side. Left side normal throughout.

Lower Extremities.—Atrophy, o, r = l, symmetrical. Hypertrophy, o, r = l, symmetrical. Spasm, o, r = l, symmetrical. Hypotonus, +, right greater than left. Muscular power diminished on the right side, less marked than in the upper extremities. Knee jerks, +, r = l, symmetrical. Ankle clonus, o. Achilles, reflex, + +, r = l, symmetrical, active, almost a clonus. Plantar; right, not Babinski in type; slight separation of smaller toes; large toe not flexed nor extended. Occasional plantar response; left, prompt plantar response. Oppenheim, o: paradoxial, o; Romberg, slight; Rosenbach, +; Lasègue, o. Nerve stems not painful to pressure.

Walk: Patient walks with knees spread apart, the right leg usually in advance. No asynergia. With eyes closed, no marked change in walking. No propulsion, lateropulsion, nor retropulsion.

Sensory.—Heel-knee test; slight ataxia right side, left negative. Light touch appreciated fairly well throughout; r = l. Brush not felt on right foot, left foot normal.

Pain: Pin-point and head well distinguished, mistakes much fewer than in upper extremity on the right side; left side, no mistakes. Stern test, no mistakes.

Sense of position and of limb not markedly impaired.

Temperature sense not impaired. No trophic disturbances. Cloth stuffs to feet fairly well differentiated. No loss of bone conduction in hips and thighs, but slight reduction in right foot.

Mental Examination: Patient showed no loss in attention, power to add, divide, subtract, and do complicated problems in his head. Backward associations excellent. Memory tests showed no change notwithstanding complexity; 12 numbers forward and 8 numbers backward promptly given. The only noteworthy feature, and that was slight, was the patient's apparent indifference to his serious state. He was inclined to be a little light hearted rather than serious, yet gave an impression perhaps that he did not want to appear too deeply interested. It was in part this approach to the *belle indifference* that perhaps led to the feeling at first that it was a functional disorder.

Summary.—An adult of forty with a syphilitic infection thirteen years previously, has an apoplectiform attack from which he makes a good recovery. One year later he has a second attack, without loss of consciousness, and an examination one month later shows: (1) Slight hemiparesis of the right upper and lower extremities; (2) marked ataxia in right upper, slight in right lower extremity; (3) choreoathetoid movements of right arm; (4) disturbance of pain sense, of deep sensibility, of postural sense in right upper extremity, the right lower extremity slightly but not markedly involved. No absolute loss of light touch in either extremity; (5) astereognosis in right hand, involving recognition of qualities of object as well as object itself; (6) definite though not marked pains in right shoulder. In addition there were pupillary anomalies and a possible alteration in the patient's general emotional tone suggesting a *belle indifference*. Clinically this is a fairly clear example of the thalamic syndrome of Déjerine.

The chief symptoms of this syndrome as outlined by Roussy in his monograph just quoted are: (1) A superficial persistent hemianesthesia of an organic nature, more or less marked for superficial sensibility, tactual pain, temperature, but always very marked for deep sensibility. (2) A mild hemiplegia, usually without contracture, and rapidly regressive. (3) A mild hemiataxia, and more or less complete astereognosis. (4) Severe pains on the

hemiplegic side, persistent paroxysmal, often intolerable and not yielding to any analgesic treatment. (5) Choreo-athetoid movements in the members of the paralyzed side.

The only variation, in the case cited, from the general symptomatology laid down by Roussy, are the absence of severe paroxysmal pains; in some of the cases reported these came on later than one month, and the patient's slight pains now felt may increase in severity.

Turning for a moment to the cases reported in literature, those cited by Coriat, the only ones in English literature, are latest in point of time.

Case I is probably not one of the thalamic syndrome. There was no ataxia, no astereognosis, no choreic or athetoid movements, no asymbolia, and no loss of touch localization. He had pain in the left side, hemihypoalgesia and hypoesthesia, and slight hemiplegia. Wherein this conforms to Déjerine's and Roussy's criteria it is difficult to say.

The author[23] on page 466, in describing Case I, says there is "no ataxia" and "no astereognosis," and yet on page 469 in the same article, in discussing Cases I and III, he says these two cases presented a fairly clear picture of the pure thalamic syndrome, "such as the presence of sensory disturbances, motor weakness, *astereognosis*, pain, and *ataxia*." How the author can reconcile these two absolutely contradictory statements regarding the same case, and in the same article, it is difficult to understand. Case I is not a case of the thalamic syndrome, and the meager case history does not permit a satisfactory diagnosis.

It is also extremely doubtful that Case II is one of the thalamic syndrome. The internal capsule is markedly involved both in the motor and sensory carrying fibers. There is no evidence to show that it is not an ordinary capsular lesion with sensory implications not necessarily thalamic. The pain described is "dull and heavy," not the sharp paroxysmal pain of a thalamic lesion. There is complete involvement of the entire motor-carrying portion of the internal capsule—no choreic or athetoid movements. Motor and ideational apraxia —not a part of the thalamic syndrome at all and indicating cortical-callosol involvement as well. Lesions above the capsule can produce just this picture.

Case III of Coriat's is possibly a case of the syndrome—although the choreiform and athetoid movements are absent and the pain is mentioned as a precursor of a convulsive attack and is not mentioned in the symptom picture after the onset of the convulsions. Under mercury and iodides the conditions markedly improved, writes Coriat, but he makes no distinction as to what improved save the headache. If the sensory symptoms cleared up then we have further evidence of its not being a case of the syndrome under discussion. There is enough positive evidence to warrant its exclusion in my opinion. It would be worth while for the author to give a fuller neurological and particularly a mental status.

Case IV is certainly not a case of the syndrome. There is no pain, no choreoathetoid movements, and the involvement of the motor fibers of the internal capsule was very extensive. Further, the case is complicated with sensory aphasia. Coriat only claims it as a case of the mixed syndrome, but there are serious doubts even as to this. There is no good evidence to show that the lesion is not all in the capsule, or above the capsule sensorially, and negative evidence as to the thalamus itself being involved in the classical situation as claimed by Roussy.

For these reasons I am inclined to rule all of Coriat's cases out, reserving a doubt as to my judgment on his Case III.

The cases that Coriat has described have been current in literature since Carpenter in the sixties of the last century first called attention to the optic thalamus as the seat of sensation, and their better understanding was made possible by Ferrier, Renzi, Nothnagel, Oppenheim, and v. Monakow. The later work of Déjerine and Roussy has been to isolate certain cases from among the large general group of cases like those reported by Coriat that showed fairly definite anatomical lesions and to which the name "thalamic syndrome" could be correctly attached.

It is for this reason that perhaps a detailed account of the findings in patient Jossaume of Déjerine and Egger may be given here, since it must serve as the type on which the thalamic syndrome was erected. Inasmuch as it is not available up to the present time to English reading students, a complete presentation of the history and findings in this case seems justifiable.

The patient Jossaume was first reported by Déjerine and Egger[3] in a study on incoordination of central origin. It is here given as reported by Roussy in his Thesis on the Optic Thalamus and the Thalamic Syndrome.

Obs.—Patient named P. J., 76 years of age, entered the Salpétrière, Salle Parrot, July 11, 1902, after an attack of left hemiplegia. Nothing of note in her heredity. Menses appeared at 10½, and she was married at the age of 22. Her husband died of a gastric tumor. One child, who is well. No miscarriages. No syphilis and no alcoholism. Toward the age of 60 patient was affected by a gouty rheumatism of the upper extremities. The crises became so intense that she was obliged to abandon her business. After twelve years these phenomena had retrogressed, and her general health was better.

History of Illness.—On April 1, 1902, at 7 in the morning, after having eaten well, the patient was suddenly taken with vertigo; she fell to her knees, everything about her seemed to be going round, and she then had intense and protracted vomiting. She did not lose consciousness, but was unable to take care of herself. Put to bed, she had an imperative desire to urinate, but had no power to satisfy herself. Vesical tenesmus was painful, radiating in the lower abdomen. In the evening, on her admission to the hospital Lariboisière, she was catheterized, but she obtained no relief, and notwithstanding that she was catheterized three times a day vesical pains persisted in all their intensity—becoming more and more exasperating at the period of desire and more and more frequent. This condition, which tormented the patient day and night, continued about two months.

On her admission to the Salpétrière the retention had disappeared, and had given place to a frequent imperious micturition which obliged the patient to remain constantly on the closet. In the beginning the hemiplegia was complete for the two extremities; the patient could only move her shoulders and hips. The rest of her members were inert. The facial was not involved, and there was no deviation of the mouth. Fifteen days after her attack, volun-

tary motion came back little by little, and on her admission to the Salpétrière the patient could move her arm and leg.

Actual State 1903: Notwithstanding her 76 years, the patient shows no signs of senility.

Objective Sensibility: Tactile (examined by brush). Left hemianesthesia characterized by centripetal diminution. The hand is totally anesthetic, as is also the lower fourth of the forearm. Higher up the anesthesia is replaced by a hypoesthesia which diminishes as one approaches the shoulders. In the foot there is marked hypoesthesia and centripetal diminution for the rest of the extremity. The left half of the face is anesthetic to light touch; the buccal, pharyngeal, palatine, and lingual mucosæ, and the cornea and conjunctiva of left eye are hypoesthetic. As may be noted in the accompanying chart, there was also a diminution of tactile sensibility in the right lower extremity, the which, although less marked than that on the left, is none the less very evident. [NOTE: Chart omitted here.]

Pain: Prick of pin: There was a period of three months in which pin pricks caused only dysesthesia, that is, there was no specific sensation. The point of the pin caused the sense of disagreeable formication. Actually the prick is felt as such, but less strongly on the hand and foot than on the points near the shoulders and hips. Strong excitation stirs up sensations lasting several days.

Temperature (50° C.). The trunk and the face are more sensitive to heat than the extremities on the left side. There is retardation of perception of some 14 or 15 seconds in the hand and some 15 to 25 seconds for the foot. On the forearm the retardation is reduced to 3 or 4 seconds, and the thigh and arm feel the contact with the heat almost immediately. The face is hypoesthetic to heat, hyperesthetic to cold, the same as the extremities. Pressure is felt in the fingers, although feebly, and it augments proportionately as one approaches the root of a member.

Skeletal Sensibility: The vibrations of the diapason are not felt on the left side of the skeleton; they cause, on the contrary, an intense feeling of burning even in the region where thermoanesthesia is present. The skin, on the contrary, feels the vibration of the tuning forks. Comparison of the two halves of the body shows slight involvement of the lower right limb. At this level the vibrations of the diapason are feebly felt and contrast strongly with the intensity perceived in the right upper limb.

Segmentary passive position. The position of attitude is completely lost in the left upper extremity. The patient has no idea at all of the position given to any portion of this extremity. Flexion or extension, adduction or abduction, pronation or supination are not recognized.

In the digits of the left foot the sense of attitude is enfeebled. The patient, although feeling the passive motion, cannot indicate exactly the nature of the movement. The same thing is true for the knee joint. For the right leg the idea of passive movement and of passive attitude is conserved. In short, there is abolition of perception of passive movement and attitude in the left upper extremity, and diminution of the same perceptions for the left lower extremity.

Stereognostic Sense: Astereognosis of the left hand is complete; the patient does not recognize the form, nor the physical properties of an object and cannot name it. The sense of weights is completely lost.

Subjective Sensibility: Since the attack the patient complains day and night of active continuous pains, occupying the left half of the face and radiating into the arms. At the moment of the crisis it seems that the left eye is being torn out and that something is pressing on the orbit. The temple, auditory canal, the left half of the tongue and mouth are the seat of paresthesiæ and of intense burning. The same is true for the left nostril.

Motility: All of the movements of the left extremity are perfectly conserved; the muscles of associated movements, as well as isolated and specialized movements. The musculature of both extremities is soft and shows neither contractures nor hypotonus. As to the muscular force, it is considerably diminished. Flexion of the forearm on the arm brings out slight resistance; all the other segmentary positions of the leg and arm are easily overcome. As to the muscular force of the left lower extremity, it is also considerably diminished if one compares it with that of the right arm. It is easy to overcome the resistance of the flexor, and of the extensors of the leg on the thigh. (The last are a little stronger than the former.) The plantar and dorsal flexors are similarly weak. There exists a light paresis of the left of the mouth. On pressing the puffed out cheeks the air escapes to the left side of the mouth. No trace of paresis in emotional mimicry.

Reflexes.—The knee jerks and Achilles reflexes are exaggerated on both sides, but more on the left than right, biceps, triceps, radials, and flexor reflexes equal on both sides. Babinski negative but cutaneous plantar reflex present both sides. Tickling of the plantar surface of the right foot produces dorsal flexion of the right foot, and at the same time of the left foot, although excitation of the left plantar alone determines a dorsal flexion of the foot of this side.

Choreic Movements.—There is further to note that the left arm of the patient is from time to time animated by a choreic trembling. This tremor consists of small movements of pronation and of suspination, of flexion and of extension of the arm, of the hand and of the fingers. One can readily bring it on by faradization. Even the evocation of the sensori motor image of the arm suffices to make the movements appear. If, for example, one asks the patient to inform us of the position of his arm, it commences to enter into choreiform movements, movements which the patient feels, but which she is unable to control and to arrest. The attempt to stop them makes them worse. In turning the patient's attention by asking her questions which bring out other images, the movements are arrested.

Hemiataxia.—Hemiataxia of the left side is manifest, but the patient, after a certain hesitation, succeeds in carrying her index to the top of the nose with the eyes closed. She can also limit the incoordination as the object nears attainment.

Eye.—Beginning cataract of both sides. Traces of ancient hemorrhages in the left retina. No pupillary irregularity. Reflex to light normal. No dyschromatopia, achromatopsia, no hemianopsia, no limitation of the visual fields. Slight nystagmoid movements of both eyes in extreme lateral position left and right. No external ophthalmoplegia.

Hearing.—Slight diminution on left side.

Smell.—Slight diminution in left side.

Swallowing.—One observes troubles in swallowing in this patient. When she wishes to take a swallow of milk, for example, she is obliged to take

it in three or four fractions. The same is true for solid food, even when well chewed and divided. She experiences a certain difficulty in transferring the bolus into the pharynx. Objective examination reveals no paralysis, or paresis of the palate, the tongue, or of the pharynx. The patient complains further of a continued dryness of the left side of the mouth (xerostoma). She seems to lack saliva to moisten her food and when she eats it is always on the right side that she holds her food.

General State.—Nothing particular to notice in the thoracic or abdominal viscera. The heart, liver, and kidneys are normal. No sugar nor albumen in the urine. Pulse, 66. Intelligence is active and lucid and the patient replies perfectly to all questions that one can ask her and gives evidence of perfect judgment.

Autopsy, March 18, 1904.—Normal cortex, nothing to note in the meninges. The left hemisphere presents nothing of importance. The right hemisphere is normal in aspect, and in volume. One can see on the ventricular wall at the level of the thalamus an ochracheous cicatrix. On horizontal section, following a line passing superior to the optic thalamus and to the corpora striata one sees an ochracheous focus as large as a nut, in the posterior portion of the thalamus and penetrating into its depth.

The right pyramid is a little smaller than the left. Several granular bodies on the left lateral cord of the cord in the fresh state.

After 48 hours in 1 per cent. formal the pieces were placed in Müller's fluid and left for hardening five months for the brain and three months for the cord.

The results of an anatomical study (p. 249) shows: (1) The seat of the central lesion which is capable of giving the picture of the thalamic syndrome. (2) The consecutive secondary degenerations.

Primitive Lesion.—This occupies the posterior and external part of the optic thalamus at all its levels but does not go beyond it above or below. As a matter of fact, in the upper portion of the thalamus the lateral internal and external (mesial) nuclei are destroyed in their posterior third (section 416). Lower, the focus diminishes in extent, involves always with predeliction the external lateral nucleus, and in the sections passing above our series, 416, one sees that the primary focus disappears rapidly in extent and disappears at the superior level of the thalamus. This lesion involves principally the posterior third of the external (lateral) nucleus of the thalamus, which it destroys entirely. It encroaches within upon the internal (median) and median (NLVI of Marburg) nuclei and behind upon the pulvinar. At the inferior part of the optic thalamus (section 325, Fig. 64) the lesion is represented only by a trail traversing right through the external (lateral) and internal (median) nuclei.

From without and in all its levels it sections the posterior part of the posterior segment of the internal capsule and the posterior portion of the lenticular nucleus.

In the superior thalamic region (section 416) it also wounds the retrolenticular segment of the internal segment.

Secondary Degenerations.—(*a*) Above the lesion there exists a degeneration of the posterior part of the posterior segment of the internal capsule, which one can follow from below above just to the base of the corona radiata, and which may be followed in this to the base of the convolutions. This degeneration is difficult to interpret. Is it a retrograde degeneration, consecutive to a lesion of the capsule, or an ascending corticopetal degeneration of the thalamo-cortical fibers? It is possible here that the two processes are at work. But also, as we have seen, the cases of old lesions of the thalamus, like this one, are unfavorable to the demonstration of the existence of thalamocortical fibers. The method of Marchi permitted us to well establish them in the animal as in our monkey 1 and in man. (Case of Kaiser, Obs. IV.)

(*b*) At the level of the lesion (thalamic region). There are involved by the primitive focus and from the degenerations following at a greater or lesser distance. (1) The radial fibers of the different nuclei of the optic thalamus. (2) The internal (median) and the external (lateral) medullary laminæ of this organ. (3) The internal (median) and supplementary medullary laminæ of the lenticular nucleus in their posterior portions. (4) The striothalamic and thalamostriate fibers destroyed by the capsular lesion. (5) The vertical projection fibers of the internal capsule. (6) The fibers of the sagittal layer of the parietal lobe in small numbers.

(*c*) Below the lesion (subthalamic region). In this region, apart from the light coloration, noted apropos of section 266 (Fig. 65) we have seen that the ansa lenticularis, the lenticular bundle, the fibers of the region of the median lemniscus and a contingent of the subthalamic striæ were perfectly intact.

(*d*) In the encephalic trunk. In the pes pedunculi, the degeneration of the pyramidal tract is limited to the external second fifth. Outside, the Türck's bundle is absolutely normal. This pyramidal degeneration goes through the pons and the medulla to the cord where it is less marked in the direct, but very distinct in the crossed pyramidal tracts. The lemniscus is normal in the tegmentum of the peduncles, pons, and medulla. There is absence of atrophy of the median lemniscus, notwithstanding the extent of the thalamic focus and the age of the lesion (2 years).

This case shows:

(1) As to the different clinical signs the patient shows on the left side: Superficial and deep hemianesthesia, a hemiplegia which regressed rapidly, mild hemiataxia, astereognosis, severe and persistent pains in the paralyzed side, corresponding anatomically to a primary lesion of the optic thalamus destroying entirely the posterior third of the external lateral nucleus, encroaching within on the internal (median) and median nuclei, behind the pulvinar and sectioning from without the posterior segment of the internal capsule and the posterior part of the lenticular nucleus.

(2) That a lesion of the posterior part of the posterior segment of the internal capsule, such as we have here, does not give very marked motor disturbances and such are not any more pronounced in the lower extremities than in the upper. There does not then seem to be in the internal capsule the grouping of fibers corresponding in stages to the distribution of the motor zone as the experimental facts of Horsley and Beevor (Translations of the Royal Society of London, Vol. 181, 1890) would seem to prove in the work upon monkeys. The anterior part of the posterior segment of the internal capsule corresponding to the upper limbs, the posterior part to the lower limbs. Anatomical clinical facts do not correspond to this classical notion; ours

are an evident demonstration of and lend support to those enunciated by Pierre Marie. (*Semaine Méd.*, 1902.)

Before closing, attention should be called to Roussy's latest communication in which he makes a division into a pure and a mixed thalamic syndrome. The symptoms and the findings in the pure syndrome have been discussed. Here the internal capsule may be slightly involved or not at all (Case Kaiser, Roussy Thesis.) In what particulars does the mixed syndrome differ from the type? In this latter (Roussy[22]) the paralytic troubles are more marked, assuming the character of a spasmodic organic hemiplegia to which have been added the clinical signs of an exteriorization of a lesion of the optic thalamus, with superficial and deep hemianesthesia, astereognosis, and pains. The difference anatomically consists in a greater encroachment on the fibers passing in the internal capsule.

Further, Haskovec proposes a tripartite division of these cases into (1) sensory thalamic, (2) sensory motor thalamic syndrome, and (3) sensory-sensorial and motor with hemianopsia.

The use or validity of Haskovec's division is difficult to see since one could go back to Carpenter's observations in the sixties and arrange all of the organic hemianesthesias according to Haskovec's scheme. His suggestions are purely hypothetical and thus far lack anatomical foundation.

It would lead one too far afield to discuss all of the cases of hemianesthesia without motor, or with slight motor involvements. v. Stauffenberg has recently gone over this ground very thoroughly. He demonstrates anew that the thalamo-cortical paths may be interrupted above the capsule and give the signs of hemianesthesia and analgesia. The sensory changes alone are not sufficient to permit a diagnosis of the syndrome, as Coriat has apparently done.

The numerous studies on hemichoreic movements are in need of revision. Roussy in his thesis is inclined to attribute them to the capsular lesion but the tendency is to call upon the red nucleus and cerebellar connections more and more for the interpretations of some of the choreic and paralysis agitans-like tremors.

The present available studies on this syndrome are about a dozen. These are here given in a short running bibliography.

CASES OF THE THALAMIC SYNDROME REPORTED IN LITERATURE.

1. Graeff: *Archiv f. Psychiatrie*, 14, 1883, p. 598. This case was complicated by cerebellar hemorrhage.

2. Edinger: *Deutsche Zeitschrift f. Nervenheilkunde*, 1, 1891, p. 266. In this case there was hyperesthesia, rather than anesthesia. Déjerine and Roussy both include it, but chiefly from a historical sense. Anatomically there was a hemorrhage into the dorsal portion of the external (lateral) nucleus of the thalamus and the pulvinar.

3. Déjerine et Egger: *Revue Neurologique*, 11, 1903, p. 397; incorrectly cited as 1893 by Roussy in his monograph and by Déjerine in their 1906 paper. This contains the original clinical description of the case Josseaume which is the type case.

4. Thomas et Chiray: *Revue Neurologique*, 12, 1904, p. 505. A case P. reported in extenso: Cited by Roussy. Microscopical series not yet reported on.

5. Dide et Durocher: *Revue Neurologique*, 12, 1904, p. 802. Note communicated by the Secretary of the Paris Neurological Society, Henry Meige. The anatomical findings are reported in brief.

6. Long: *Rev. méd. de la Suisse Romande*, 1904, p. 791. A short note only. Case reported in extenso in Roussy's thesis. No microscopic report.

7. Haskovec: *Revue Neurologique*, 12, 1904, p. 1148. Note presented by Déjerine on two cases. No microscopical findings.

8. Bourdon et Dide: *L'Année Psychologique*, 11, 1905, p. 40. One of three cases reported in a study on tactile sensibility in organic hemiplegia. No autopsy.

9. Déjerine et Roussy: *Revue Neurologique*, 14, 1906, p. 521. This contains the clear presentation of the syndrome with a short summary of the findings in three cases. Josseaume, Hudry and Thalman, all of which are reported in extenso in Roussy's Thesis.

10. Long et Roussy: *Revue Neurologique*, 14, 1906, p. 1202. Report of case Kaiser further studied by Roussy in his Thesis.

11. Roussy: La Couche Optique; Le Syndrome Thalamique. Thèse de Paris, 1907. The author has here given an extensive experimental study on the thalamus and further has given greater precision to the syndrome as originally conceived. It contains in addition to the thalamus studies the full detailed account of four cases with the syndrome with complete microscopical analysis of the lesions. Three observations without autopsy, two already cited here (Thomas et Chiray, Long) and one new one "Garn." It also cites the observations of those already listed here.

12. Claude et Rose: *Revue Neurologique*, 15, 1907, p. 183. A peculiar history with tumor, hemiplegia, and the thalamic syndrome. No anatomical details.

13. Lejonne et Chartier: *Revue Neurologique*, 15, 1907, p. 410. An irregular general paresis with a transitory picture of the syndrome. No anatomical details.

14. Déjerine: *Gazette des Hôpitaux*, 80, 1907, p. 999. A clinical lecture with presentation of case.

15. Winckler u. London: Cited by Roussy, *Revue Neurologique*, 1909. Koninklyke Akademie v. Wetenschapper, Amsterdam.

16. Vincent: *Revue Neurologique*, 16, 1908, p. 553. An interesting clinical example of the syndrome with possible cerebellar symptoms added. Discussion by Roussy. No anatomical report.

17. Hartenberg: *Presse Médicale*, 1908, p. 33. Clinical Lecture.

18. Massolongo: *It Policlinico*, 14, 1908, p. 333. Clinical Lecture.

19. Klippel, Segueeff, Weil: *Revue Neurologique*, 16, 1908, p. 694. Full case report. No anatomical details.

20. Haskovec: *Revue Neurologique*, 17, 1909, p. 53. Case history, with no microscopical study. The author here suggests his triad of groups already mentioned.

21. Conos: *L'Encéphole*, 1909, p. 468. Case history.

22. Roussy: *Revue Neurologique*, 17, 1909, p. 301. Case histories of two patients with autopsies. Roussy in this paper proposes the terms pure and mixed syndrome. He also criticises Haskovec's studies.

23. Coriat: *Journal of Nervous and Mental Disease*, 36, 1909, p. 462. Clinical notes on four cases, three of which are probably not cases of the thalamic syndrome.

24. v. Stauffenberg: *Arch. f. Psychiatrie*, 45, 1909, p. 683. A full discussion of hemianesthesia without motor defect, report of two cases; the first not one of the syndrome, with autopsy—cortical defect, the second, probably of the syndrome—no autopsy.

64 West Fifty-sixth Street.

THE INFLUENCE OF ALCOHOL IN CERTAIN DISEASES OF THE SKIN.*

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

Alcohol is a poison; taken pure and in sufficient quantity it pretty promptly destroys life, after causing loss of consciousness, profound muscular relaxation, and diminished respiration, with lowering of temperature. And yet in one form of dilution or another alcohol is in well nigh universal use over a large portion of the earth, especially in the temperate zones; for in the extremes of heat and cold its employment is so disastrous that it is commonly avoided.

So much has been said and written in regard to the effects of alcohol on the system that there is no need of great enlargement on the subject at this time. But it is interesting to note that relatively lit-

*Read before the New York State Medical Society, January 25, 1910.

tle is said in regard to its beneficial action, whereas any amount of evidence has accumulated concerning its harmful effects on all the tissues of the body; although much evidence has also been often collected showing apparently good results from the moderate use of some alcoholic beverages, temporarily at least.

But experimental study has established the fact that alcohol certainly has a prejudicial effect on cell life, both vegetable and animal, and pathological studies have demonstrated degenerative changes in almost all the tissues of the human body as a result of the action of alcohol taken internally.

It is natural, therefore, to suppose that the skin suffers with the rest of the economy, and clinical experience shows that this is the case, often from even the moderate use of alcoholic drinks, although as yet we have not the histopathological evidence of the fact.

An interesting experimental demonstration having some bearing on our subject, is that concerning the influence of alcohol upon susceptibility to infection[1] "These various experiments are in remarkable accord, nearly all showing that animals intoxicated by alcohol are more susceptible to bacterial infection or to toxines than are normal animals, . . . and that the process of experimental immunization is unfavorably influenced by alcohol."

Another instructive line of experimentation has demonstrated in chronic alcoholism of animals, a fatty metamorphosis affecting especially the cells of the liver, the heart muscle, and the kidney; also changes in the central nervous system and degenerations of the peripheral nerves.

A great consideration in regard to the effect of alcohol in connection with diseases of the skin relates to its effect upon the capillary circulation. Now all experiment and observation show that by its sedative action on the vaso-constrictor center of the medulla, alcohol causes a slight paralysis of the nerves controlling the capillaries of the skin, and the sense of flushing after its use in any quantity is well recognized. This dilatation of the cutaneous capillaries leads to a greater flow of blood to the surface of the body, and of course to a greater congestion of diseased portions, which congestion is one of the chief features in many dermatoses most difficult to control. With this congestion there is also an increased action of the perspiratory glands, with probably a modified secretion: for all experimenters state that a certain proportion of alcohol taken in the system is given off unoxidized by the kidneys, lungs, and skin, and it has been definitely demonstrated in exhalations from the skin.

Still another result of alcohol is to be mentioned, which may have some bearing in regard to its influence in diseases of the skin, namely, its effect on muscular tissue. It has been definitely determined, both by animal and human experimentation, and by wide experience in practical life, with soldiers, workmen, explorers, travellers, and others, that while the first effect of alcohol on muscular tissue is stimulating, this is invariably followed by a relaxing or debilitating effect, which greatly lessens the production of muscular energy; this is true of both striped and unstriped muscular fibre. This fact may be of importance in connection with the muscular elements in the skin, which have much to do with its tone and its glandular system.

Finally, we have to consider the effects of alcohol upon metabolism, that is, upon the total action of the organs which have to do with the transformation of food stuffs into tissue and energy, and the final results of anabolism and catabolism, which have so much to do with many diseases of the skin.

That alcohol in appropriate quantities acts as food, and is oxidized and utilized in the production of energy, there can be little doubt in the light of the many pharmacological experiments which have been made. Being rapidly absorbed from the stomach and upper small intestine it circulates in the blood as alcohol, and quickly affects the brain and tissues, until it has become more or less completely oxidized, and has disappeared. But what the influence of the circulation of alcohol is upon the metabolic processes of the body has not been determined experimentally, and we have to rely on ordinary clinical evidence; that it does in a measure interfere with this is common medical knowledge. In this manner, therefore, it can act prejudicially in connection with many diseases of the skin.

The chemico-vital processes on which nutrition and the dynamics of the body depend are, as we know, centered around what is known as oxidation, and the presence of alcohol has been shown to interfere with this in the economy, causing a gradual waning of the metabolic activities of the body. In this manner the disposal of waste substances is hindered and delayed, with the retention of the products of catabolism and the deposit of fat, as also of fibrous tissue. Kreparsky[2] has shown that alcoholism, acute or chronic, lessens the number of leucocytes, and that the repair of wounds take place more slowly in drinkers, because of the insufficient supply of white blood corpuscles at the area undergoing healing; this observation has an important bearing in connection with our subject.

The experimental studies which have been made on alcohol have largely related to that substance pure or diluted with water, or to whisky, a relatively simple substance, and it is difficult to apply all the facts to alcohol as it is ordinarily used in daily life; though various experimenters all state that the effect of alcohol is the same, however it is combined. Practically this latter does not seem to be the fact, for all know that the free use of port and Madeira wine has, in times past, been greatly productive of gout, when the same patients can often take a certain amount of whiskey with impunity; further illustrations of the different effects of various alcoholic beverages will readily occur to every one.

In considering, however, the effects of alcohol as actually observed in dermatological practice, it does not seem that we are to regard the toxicity of the alcohol alone, for in daily life that is rarely taken pure or only diluted with water. But we are to consider rather the general subject of the influence of the alcoholic compounds in general use, recognizing, it is true, that while a large share of the effects produced are due to the alcohol contained, a certain amount is also due to the other ingredients which differentiate the various forms of drink. Account must likewise be taken of the adulterations which are shown to constantly exist in cheaper articles, and also occasionally in those of higher grade. Surely all recognize the somewhat different effects from brandy, whiskey, gin, rum, champagne, port, madeira, sherry, Rhine and Moselle wines stout, ale, beer, cider and various fruit wines, liquors and cordials, besides many others; and the different conditions produced on the skin seem also to differ somewhat, probably owing to the varied effects of other components than alcohol on the tissue, producing different effects on the various organs or

parts of the body which have to do with metabolism. This is a difficult subject to handle, and I doubt if I can make clear what I observe clinically, and there is a singular dearth of recorded facts on the subject to be found in literature.

Syphilis.—One of the first to dwell specifically on the effect of alcohol on the skin was Renault,[3] who wrote under the guidance of Hardy and Hilliaret, at the Hôpital St. Louis, Paris. He speaks very strongly in regard to the harmful influence of alcohol in syphilis, which is now a very well-recognized fact. He shows by a series of cases that, "1, alcoholism is one of the most powerful causes of the late manifestations of syphilis; 2, that these develop in spite of an antecedent mercurial course; and, 3, that syphilides in drunkards are mainly ulcerating."

Fournier has insisted on this in his clinics and, at one of the meetings of the French Dermatological Society,[4] he exhibited the case of a young woman with recent syphilis exhibiting enormous pustulo-crustaceous and papulo-ulcerating generalized syphilides, induced by the immense amount of beer, brandy and absinthe which she consumed. Elsewhere he speaks of alcohol as the natural-born enemy of syphilitics.

I will not detain you with citing any of the many cases which I have seen illustrating these points, but may observe that they are confirmed by innumerable instances, both in public and private practice. So commonly is this the case that it seems to be the rare exception to find bad, ulcerative syphilis in those who always have been teetotalers. The most important direction to give to those who have acquired syphilis is that they shall totally abstain from all alcoholic and fermented beverages indefinitely; even long after the primary infection alcohol may induce grave syphilitic or para-syphilitic affections. This is especially true in regard to late nervous diseases, as locomotor ataxia, polyneuritis, paresis, etc., as Petrini,[5] Grotte[6] and others have shown.

In regard to the action of alcohol in producing or influencing badly other diseases in the skin, there are, in the experimental developments previously mentioned, many good reasons to expect this to be the case. Renault, already mentioned, includes most of them in his Thesis, as follows: 1, "Because alcohol is eliminated by the skin; 2, because a small dose produces general nervous excitation, and a large dose depression; 3, because of its diminishing the amount of carbonic exhaled and lowering the temperature; and, 4, because of its tendency to produce fatty change in the tissues." Janin[7] goes over much the same ground, and claims that "alcoholism, by its unaided power, is capable of evoking morbid cutaneous phenomena, for which, however, there must be some special constitutional predisposition. But these effects are seldom met with; and what we most frequently observe, and should always bear in mind, in respect to this condition, is the important part it performs in the maintenance and aggravation of preexisting disease, to which it sometimes imparts a serious character."

Rosacea.—Perhaps the most striking illustration of the effect of alcoholic drinks on the skin is found in the conditions with which all are familiar on the face. Beginning with the ordinary flushing, seen after over-indulgence in wine or alcoholics, which may be transient, we have the well-known acne rosacea of continued drinkers, which after a while results in the permanent dilatation of the capillaries, seen so often especially in those exposed to the cold, as in drivers, seamen, and others. The reason why this occurs principally on the face is undoubtedly due to the paralyzing effect of the cold on cutaneous vessels greatly dilated by alcohol; with this continued excessive supply of blood there is often a more or less hypertrophy of tissue, which may cause an immense enlargement of the nose, rhinophyma.

Acne.—But this redness and enlarged capillaries are not the only lesions on the face which we often find in those who use alcoholic beverages, nor is it necessary to take the stronger liquors in order to have much eruption there. One of the worst cases of acne rosacea, with many papules and pustules which I ever saw, was in a dealer in Moselle wine, who himself partook of it very freely. In this instance it could hardly be from any impurity or adulteration, as presumably he drank that which he imported himself; and as he claimed not to be an immoderate drinker, the harmful effect was probably produced by metabolic changes fostered by the esters and other ingredients composing wine, as well as the relatively small percent (7-10) of alcohol which this wine contains.

Quite another form of acne is often seen in those who drink ale and beer, which varies in alcoholic percentage from 2 to 8 per cent. Here there is more commonly the production of a pustular form of acne, often with large, indurated and sluggish masses, and often without much intervening redness. The occurrence of suppuration may be in part accounted for by one of the experimental developments already referred to, namely, that alcohol lessens the resistance power of the organism to infectious germs. Want of space prevents my presenting details of very many cases demonstrating the effect of alcohol on acne.

It is quite possible to minimize the influence of alcohol in producing these and some other skin diseases to be referred to, on the ground that the same lesions may often be observed in very many who have never taken a drop of spirituous or fermented drink. But the same may be said in regard to any one causative influence, and it is only by wide experience and wise judgment that the influence of any special etiological factor can be determined. In the present instance the constant occurrence of a certain class of eruption in all beer drinkers, its continuance often under good treatment until the drinking habits are changed, and then its subsidence with relatively simple measures, would pretty clearly indicate an etiological connection.

Eczema.—In the all-common disease eczema we constantly see the baneful effects of alcoholic drinks, as has been recognized by many writers. Renault emphasizes this and Janin gives in detail four cases of generalized eczema as typifying conditions precipitated or aggravated by alcoholism. Donovaro[8] describes carefully a case of chronic eczema on various portions of the body in the etiology of which alcohol played a conspicuous part.

In my own private practice I am constantly seeing what I recognize to be the evil effects of alcohol on eczema, but it is somewhat difficult to give briefly an exact idea of what is meant thereby and the limits of this paper exclude the many illustrative cases which could be given. But many patients will recognize this themselves partially, and when it is made clear to them they are quite willing to forego the drinking in order to be cured. It can readily be understood how the cutaneous congestion produced by alcohol, and also the lowered nervous tone can operate unfavorably in eczema; time and again I

have seen fresh attacks brought on by indulgence in alcoholic or fermented drinks, and repeatedly I have been unable to cure the disease until these have been absolutely abandoned. In one particularly obstinate case of eczema of the fingers in a gentleman, who could not believe that the moderate claret which he drank could influence the disease, the eruption persisted most unsatisfactorily; but when he abandoned the use of claret, after long holding out, the eruption disappeared under the same treatment as before. It is probable from what I have observed, that it is not so much the alcohol, which ranges from 6 to 12 per cent and averages only 8, as it is from the acidity and irritating ingredients found in even fairly good claret. In cases of eczema where stronger alcoholic drinks are taken in excess, the eruption is apt to be pretty extensive, the surface much congested, with a serous or pustular exudate, and much burning and itching. In eczemas which are caused or excited by the more moderate use of milder alcoholic beverages, the eruption is more localized and far less inflammatory in character; in other words, it exhibits the characters of the eruption as caused by ordinary metabolic disturbances, which in this instance are induced by the particular beverage in question.

Psoriasis has been recorded by many as most unfavorably influenced by alcohol, it aggravating the eruption and causing it to itch, and being even capable of exciting fresh attacks, after long freedom from eruption. Renault gives a series of cases supporting the claim that alcohol causes a greater development of the disease and itching. Nardecchia[9] narrates three cases of psoriasis demonstrating the influence of alcohol on the appearance and entire course of the disease. According to him alcohol presents an important complication, favoring the development of severer forms of the eruption and rendering the treatment of the disease more difficult. Polotebnoff[10] in an extensive study of psoriasis, states that alcoholism is most probably a very frequent cause for the development of psoriasis, and gives two striking cases. Nielsen[11] declares that chronic alcoholism can without doubt exercise a most unfavorable influence upon existing psoriasis, since the most extensive and most frequently returning eruptions are seen in heavy drinkers, and that it can cause an universal outbreak, or dermatitis exfoliativa. Also that the disappearance of the eruption will also follow quickly under treatment when alcohol is withheld. On the other hand, White[12] of Boston, at the American Dermatological Association, stated that in his opinion alcohol had no influence on the causation or course of the disease in general, but in exceptional inflammatory crises or types it becomes of temporary influence; while Drs. Jackson, Allen and Robinson held the opposite opinion.

Personally, there is not a doubt in my mind but that alcoholic beverages are of the very greatest importance in connection with psoriasis. Time and again, both in public and mainly in private practice, I have seen outbursts of the eruption following excesses in this direction, and in dozens of instances the eruption has been congested, inflamed, and itchy while they were persisted in, and then yield wonderfully when all alcoholic or fermented drink were absolutely excluded. Of this I could give any number of illustrative cases; so that I am not willing to treat a case of psoriasis in private practice unless this course will be followed.

Erythema.—Alcohol has also been reported as favoring other changes in the skin. Kaempfer[13] records in full the case of a man who was a hard drinker, in whom two liqueur glasses of cognac brandy produced a diffused redness of the face, extending visibly backward over the ears and congesting the oral mucous membrane, the pharynx being scarlet red; there was also great hyperemia of the fundus of the eye and retinal vessels. The condition lasted half an hour attended with slight rise of temperature, pulse 124 with pains in the head and a feeling of heat. The experiment was made many times, to see if the affection was caused by cognac, and each time the same phenomena occurred.

Renault devotes some attention to what others had noticed (Nobile Santo in 1841, and Lendet in 1867), and which Prof. Hardy endorsed, that alcohol can excite an eruption so strikingly like *pellagra* that it has been named pseudo-pellagra. The erythema of the exposed surfaces begins in the spring, resembling sunburn, and is followed by peeling which may last for weeks, or even months until August or September; the skin darkens and becomes like parchment, and accidental lesions, pustules and fissures may appear.

Morrow[14], in a letter from the Sandwich Islands, described what is known as the "ava" skin; this is a slightly narcotic, intoxicating drink made from the root of the ava or "kava-kava." Its irritant effects on the skin are manifest by the production of redness and dryness, with exfoliation of the surface in the form of white, branny scales. The skin is loose and wrinkled from an apparent absorption of the subcutaneous layer of fat. In old ava drinkers the entire body becomes emaciated and the skin is covered with large scales, which on falling may leave ulcerated surfaces, resulting in permanent scars.

Angioneurotic Edema.—Oppenheimer[15] reports a case of relapsing angioneurotic edema, mainly on the face and hands, in a young man 23 years of age, exceedingly obstinate, worse in summer. The author claims that the eruption was due to the use of alcoholics; a relapse was observed after the patient had taken "a couple of glasses of whiskey and soda water." The only alcoholic beverage the patient could take with impunity was claret mixed with water. Mastermann[16] warns against the danger of the use of alcohol in those with *phagedenic carbuncle.*

Gaston[17] has described a peculiar anesthesia occurring in alcoholic patients with prurigo, and claims that one can almost certainly diagnose alcoholic intoxication from the anesthesia of the parts affected. Together with violent itching night and day, but especially at night, with insomnia, night-mare, etc. there is profound anesthesia with irregular distribution. He attributed it more to the alcoholics containing aromatics, ethers, essences, such as absinthe cordials, etc. He had observed it in both men and women.

Lemoine[18] describes a case exhibiting derangement of sensibility with analgesic superficial panaris caused by alcohol irritating the nervous centres, and Lussana[19] writes of the paralyzing effect of alcohol on the cutaneous nerves.

It is thus seen, both from pharmacological experimentation and from clinical experience, that alcohol and the various compounds containing alcohol have very decided effects upon the skin, and that it is an agent to be by no means disregarded in connection with dermatoses of various kinds. For want of space I have not attempted to add much

from my own experience, but I can abundantly confirm all that has been quoted from others and could give any number of illustrative instances. I am not prepared to say that it is always the direct effect of alcohol on the skin itself which influences skin lesions, although this is often a most important factor. In a goodly proportion of cases, however, I believe that it is the disturbing action of alcohol and other ingredients of what we know as alcoholic beverages, upon the general system, including all the organs which are concerned in nutrition, and upon the processes of metabolism. This appears to be the case because we are so constantly seeing practically the same cutaneous conditions arising from gross errors in eating and drinking of other than alcoholic beverages. Thus, acne in young girls who have never touched even wine, will often be kept up by the free taking of milk in connection with food, and will then cease, under the same treatment as before, when once this error is corrected. But distilled and fermented drinks are a far greater factor in connection with many troubles on the skin than many are disposed to admit.

Alcohol Applied Locally.—Another aspect of the effects of alcohol as observed in dermatology relates to its local use therapeutically, concerning which there have been many reports that cannot be long dwelt on. Dating back even to Scriptural times, we learn of the treatment of wounds by means of alcohol or its compounds; thus, "pouring in wine" was a common practice in ancient times. We know that even up to quite a recent period the Hebrew operator in circumcision would staunch the hemorrhage by taking a mouthful of wine and holding the bleeding organ in the mouth for a short while. (It was from this practice that many cases of circumcision chancre have occurred in the past.)

Various suggestions have been made from time to time in regard to the local use of alcohol to the skin and it has attained a pretty definite position of usefulness in connection with antisepsis in surgery; its bactericidal qualities are now well recognized. Its antidotal action to carbolic acid is to well known to comment on, and many an otherwise bad burn of the skin from carbolic has been averted by the prompt application of alcohol.

Wilson[20] called attention to the value of alcohol as a refrigerant for subduing the heat and burning of local inflammation, especially in a diluted form as an evaporating or cooling lotion. Alcohol is also of valve in various combinations for application to the skin and scalp.

Salzwedel[21] advises alcoholic applications in phlegmonous and similar inflammations as follows: After cleansing with ether thick layers of cotton, saturated with 90 per cent alcohol, are laid on the part and covered with impermeable material, perforated so as to hinder but not to completely prevent evaporation. He claims good results, the fever abating and suppuration being materially quickened.

Heuss[22] recommends compresses with alcohol in a variety of inflammatory processes, sycosis, furunculosis, indolent ulcers, whitlow, etc. He uses 6 to 8 folds of gauze wet in a 95 per cent alcohol, with an impermeable dressing over it, and claims a quieting, softening, and antiphlogistic action better than with any other dressing. Romme[23] endorses all that Salzwedel, Schmidt, Loew and Heuse have written on the subject, and believes that if applied early it allays inflammation in the subcutaneous tissue and prevents the production of pus; when used later it favors its pointing in a good place. In addition to its serving as a moist dressing, he believes that alcohol also acts favorably by virtue of its hygroscopic powers.

Kaufmann,[24] collecting together 52 writings concerning the external use of alcoholic preparations, shows that the method which Salzwedel had brought forward was one of great antiquity, and that alcohol had long played a conspicuous part in local medication, from its power as a deodorizer.

Sswekjew[25] further endorses the method of using alcohol compresses in various inflammatory processes of the skin and subcutaneous tissue, mentioning the work of Lanz and Hebra, junior, in this connection.

Albert Kaiser[26] treated 93 cases of various inflammatory affections with alcohol dressings, and reports that nothing better could be desired. He uses a 94 per cent alcohol on compresses of a peculiar kind made by a German firm, covered with an impermeable dressing; the part is first freed from all fatty matter by means of benzin and alcohol.

Unna[27] asserts that as far back as 1882 the introduction of the alcohol spray exerted a noteworthy influence in the treatment of eczema. As the effects of the latter is transient, however, he spent some years in producing a permanent alcohol dressing, having used the ordinary evaporating methods and those with impermeable dressing. The composition which he recommends is ℞ stearinate of soda 6, glycerin 2.5, alcohol ad 100. This can be used where a bandage is impracticable, has high bactericidal powers, and is free from irritant action.

Lauder Brunton[28] states that the application of absolute alcohol will check the itching in pruritus ani.

Dupas[29] advises a 90 per cent alcohol for the treatment of herpes, as Leloir, his master, had already done in 1885. He claims that in the erythematous stage the eruption disappears in a few hours, and when it has reached the stage of vesication it yields in a few days; not only was this used by Leloir in febrile herpes, but it was found also effective in herpes zoster. Later Leloir advises the addition of a small proportion of carbolic acid, which lessened even more the burning sensation and pain. The application is made by pads of cotton frequently renewed during the day. He brings forward some very convincing cases in support of his views.

Hebra, junior,[30] reported at the Vienna Dermatological Society the treatment of six cases of lupus erythematosus by means of very frequent applications of alcohol, 40 to 50 times a day, of which five cases were cured. Kohn, at the same meeting, reported the case of a 23-year-old girl which he had treated in this way with brilliant results. Kaposi and Neumann endorsed the method, recalling that the elder Hebra treated the disease with a tincture of green soap.

Cantoni[31] reported the cure of favus by continued applications of rectified spirit. He claims that the alcohol penetrating the epidermis acts as an energetic parasiticide. This would seem doubtful in view of the fact that alcoholic solutions of mercury, etc., are often used without any very special brilliant results.

Finally, as an illustration of what has been attempted with alcohol, we may mention that Abrahams[32] reports the treatment of acne rosacea with subcutaneous injections of 95 per cent alcohol, 20

to 30 drops, repeated at the most three times a week. He claims that there was a brief anemia produced by the injection, followed for several hours by a hyperemia, by which obliteration of the dilated vessels was accomplished, but only after two or three months. It is questionable if others will endorse such a treatment.

Achondroplasia in a Twin.—R. Hutchison reports a case of achondroplasia in a child of 1½ years. The point of especial interest in the case was that though the child, a female, was a marked case, the twin brother was quite normal.—*Proceedings of the Royal Society of Medicine.*

A Case of Monodactyly.—R. Hutchison reports a male child of 13 weeks. The child had but one digit to each hand and each foot. The father, two uncles, one aunt, grandfather, great-uncle, and one first cousin all showed the same abnormality.—*Proceedings of the Royal Society of Medicine.*

SOME REMARKS ON COMPENSATORY DIARRHEA.*

By GEO. M. NILES, M.D.,

ATLANTA, GA.

LECTURER ON PHYSIOLGGY, ATLANTA SCHOOL OF MEDICINE; GASTRO-ENTEROLOGIST TO THE TABERNACLE INFIRMARY.

During the last twenty years I have frequently observed diarrhea occurring during certain courses of perverted metabolism, in which there was not only no local lesion to account for the diarrhea, but where it seemed to be salutary in its effect. This form has been denominated compensatory diarrhea, and, as a manifestation of morbid conditions entirely different from those usually provoking this intestinal disturbance, it would seem worthy of consideration.

The simple term diarrhea is usually applied to the too frequent discharge of more or less fluid stools, but we should remember that there is a marked variation in the individual in this respect. Many there are whose bowels move from two to three times daily, with no apparent impairment of health; while others consider themselves normal with one movement every forty-eight hours. When, however, the peristalsis, normal to the individual, is accelerated, the stools become too frequent and too watery—the latter due to either an over supply of water or increased secretion from the mucous membrane of the intestine. "Any condition that hastens the movement of the contents, especially in the large intestine, therefore, tends to cause the feces to be more liquid." The etiology and pathology of the diarrheas brought about by irritating or decomposing ingesta, or inflammatory states of the intestinal mucosa, need not be discussed here, but that form instead, where the toxic products of catabolism are simply being washed out with neither material harm to the bowel, nor systemic shock.

In looking up the literature on compensatory diarrhea, I was surprised at its paucity. I have now in mind two books purporting to cover the field of intestinal disorders, where it is not mentioned, while in four of the standard works on practice it is touched on only incidentally as a symptom of uremia.

Dr. Henrich Stern of New York has contributed an excellent study of this condition (*Journal of the American Medical Association*, Aug. 8, '08), and I shall use his classification of types as being, in my opinion, both correct and complete. "First, diarrheas which are concomitant with deficient or perverse catabolic processes. Second, diarrheas which are consequences of functional or structural diseases of certain excretory organs. Third, diarrheas occurring during the period of systemic physiological decline." As illustrative of the first type may be mentioned the diarrheas of gout, Addison's disease, diabetes, goiter, and, according to some authorities, pellagra. The second form of compensatory diarrhea may present itself as a concomitant of impaired renal function, or as the result of extensive burns, especially those over the abdomen.

That certain diarrheas, not exhausting, but rather grateful in their effect, are not infrequent in old people, will be noted by all careful observers, and I have under treatment at present a hale old gentleman, who welcomes his fortnightly diarrhea as a salutary visitation. In all these forms of compensa-

*Read at a meeting of the Chattahoochee Valley Medical Association, West Point, Ga., January 12, 1909.

tory diarrhea the discharges from the bowels consist in the main of "incompletely or perversely catabolized substances, or catabolic products normally excreted by other emunctories."

It may also represent certain toxic states of the blood with secondary elimination of toxins through the intestinal mucous membrane. We should not forget that it is possible for an irritative diarrhea to occur simultaneously with one of a compensatory nature, or that secondary inflammatory lesions of the intestinal mucosa may merge this beneficial drainage into an exhausting process; and it can be readily understood how the passage of these toxins from the blood, plus other excrementitious substances, may intensify the diarrhea, and transform the disturbance into one of a non-compensatory character.

In the first type, where there is either a decrease or perversion of catabolism, the loose movements generally come on abruptly, without apparent cause, give rise to but little pain or tenesmus, and, after one to three days, cease just as abruptly. Should the diarrhea last longer than three, or possibly four days, anatomic lesions will probably ensue, placing it in a different class, and calling for appropriate treatment. Often in gouty individuals, past middle life, corpulent, and averse to physical exercise, an occasional unloading of waste products, not only promotes comfort, but greatly aids the kidneys, deluged as they are by urates and alloxur-bodies. In exophthalmic goiter it has been frequently noted that after a brief diarrhea the forcible throbbing in the arteries, unpleasant flushes of heat, and profuse perspiration, especially the last, will be decidedly benefited for a while. During the course of Addison's disease attacks of compensatory diarrhea may occasionally be in evidence, but it should be remembered that in this affection diarrhea may be one of the terminal symptoms, exhibiting pain, retraction of the abdomen, and features suggestive of peritonitis. (Ebstein.) The frequent diarrhea in diabetes is open to some doubt as to being a compensatory phenomenon, for it is generally but the manifestation of intestinal indigestion, or, as called by one writer, the expression of alimentary insufficiency. To a degree, however, when there are evidences of toxic accumulations in the body, it is safe to consider the watery evacuations as corrective, and not to be hastily interfered with.

Whether or not the diarrhea of pellagra is compensatory in any stage is a question by no means clear. Certain it is that later on in the disease there are quite sufficient anatomic lesions of the intestines to fully account for this marked disturbance. I have conferred with several pathologists who have studied this protean malady from its first symptom to the autopsy, but did not find a unanimity in their opinions. Drs. R. T. Dorsey and Claude A. Smith of Atlanta do not believe the diarrhea to be compensatory at any time, but Dr. E. C. Thrash of this city admits that, while the later diarrhea is irritative, he also considers its etiology of central origin, and that probably the earlier intestinal disturbances are compensatory in character. Another view presenting itself to me, but which I am not yet prepared to demonstrate, is that the dry and scaly skin, entailing a great diminution of tegumentary excretory power, would naturally call for a vicarious activity of both the bowels and kidneys. The resident physician of one of the local sanatoria has reported to me a recent case of pellagra coming under his observation, where the patient seemed to be progressing favorably, but on checking his rather profuse diarrhea, he went into coma, dying in about twenty-four hours.

It has been noted by many that within two days after a burn, not necessarily deep, but covering an extensive area, a very watery diarrhea often occurs, followed by an improvement in the shock and clearing up of the mental hebetude or coma. This is evidently a vicarious elimination of autotoxicoses, and it is probable that, in addition to the curtailed activity of the skin, there are also some poisonous gases generated in the body, which are discharged through the bowels along with the other catabolic products. The latter is an assumption not yet fully proved. The colliquative diarrhea supervening after a long confinement from a burn, resulting from both ulcerated intestines and systemic exhaustion, is generally a terminal symptom and not at all compensatory.

I think that in uremic intoxication we note the most frequent compensatory diarrhea, though this symptom is hardly as common as the vomiting. As far back as 1859 Treitz claimed that the intestinal irritation occurring in the course of nephritis was produced by ammonium carbonate formed in the intestinal tract by the urea excreted into it. This irritation may progress until catarrhal enteritis, and, later on, uremic ulcers are present, provoking continuous intestinal disturbances not compensatory in their nature. The latter form should be easily recognized by the fetid stools containing shreds of mucus, streaks of blood, accompanied by pain and tenesmus, and followed by no amelioration of the constitutional symptoms. Hirschler has shown that ammonium carbonate is both a peripheral and central intestinal irritant, while urea and sodium chloride cause increased peristalsis by peripheral irritation alone, thus accounting in part for some of the sudden diarrheal seizures. The diarrhea in uremic conditions, therefore, where there are no decided inflammatory changes in the intestines, may generally be regarded as compensatory, and treated as such. Clinically we have all observed the speedy improvement in either threatened or present uremic explosions, after several profuse watery discharges from the bowels.

In old people, especially women past the climacteric, we notice occasional attacks of diarrhea, apparently unprovoked by dietary indiscretions or atmospheric changes, brief, painless, and followed by no exhaustion. This periodical washing out of catabolic products is probably due to the fact that the tegumentary eliminative functions in the old of both sexes are incomplete, while in some women the body continues to require that occasional readjustment formerly afforded by the menstrual flow.

Viewing compensatory diarrhea as a factor for good, its chronicity may be welcomed. To a certain extent it fills the same useful place as the safety valve on a steam engine, "popping off" when the pressure gets dangerously high. When, in the several conditions mentioned, this bodily safety valve shows its ability to "pop off" at intervals, the probability of a sudden fatal termination is much lessened. As a general rule, when the physician feels that this compensatory process is well established, he may venture a much more favorable prognosis as to the danger of fatal dyspnea, convulsions, or coma, and may hold out to his patient the hope of a material prolongation of life.

Regarding the treatment there is little to be said, as the very name compensatory stamps it as a salutary phenomenon, and one that should not be inter-

fered with unless there is a weighty reason. The local irritation produced by the passage of these excrementitious products through the intestinal mucosa is usually a small matter compared with the systemic benefit obtained; and, unless the diarrhea shows a marked tendency to set up an acute irritation or ulceration, or becomes decidedly exhausting in its nature, no therapeutic measures to check it should be invoked.

I am confident that many a sufferer, just about to reach a temporary haven of safety, has been cast back into the breakers of autotoxemia by well-meaning but unwise efforts to halt a diarrhea set up by the *vis Naturae medicatrix,* our most useful handmaiden.

This subject should appeal to every physician, no matter what line of investigation is of special interest to him, and I trust that this brief presentation of a not too well understood phenomenon may stimulate others in worthy efforts to clear up the many obscure points in the etiology, pathology, and clinical manifestations of compensatory diarrhea.

CANCEROUS AND NON-CANCEROUS PYLORIC OBSTRUCTION.

By ALEX. GOLDMAN, Ph.G., M.D.,

NEW YORK.

ASSISTANT, VANDERBILT CLINIC.

There being no medical help for cancer of the stomach, the question arises, what is the duty of a physician towards his patient in such cases? Surgery has done something in these cases which medicine cannot do. But surgery can be of help only when the disease is in its early, or, at least, not in its very late stages. While in all other diseases it behooves the physician to do everything before referring the patient to a surgeon, in pyloric obstruction this must not be done. The mere suspicion of an obstruction to the passage of food from the stomach into the intestines, or even its retardation, should put us on guard against this most dreadful disease, the one disease in which the slightest mistake, or even postponement of proper treatment, will cost the individual his life. All retardation or obstruction to the proper passage of food, all return of food by vomiting a few hours after meals, or obtaining of food from a fasting stomach by the tube, should be looked upon as a case of pyloric obstruction with a possible carcinoma, and the burden of proof of its absence must remain with the examiner.

That many cases of pyloric ulcer terminate in such thickening as to cause actual tumors, and that these same cause obstruction by narrowing the lumen of exit, is an acknowledged fact. It is also accepted that cancer may become engrafted on the tumor, or the tumor may degenerate eventually into a cancer in many cases. "Out of all cases of cancer of the stomach over 75 per cent. are implantation of cancerous growths upon a chronic ulcer" (James Spencer Brown, Medical Record, January 23, 1909). In which cases such a pylorus will become carcinomatous and in which not, is the question that faces us. Is there any way for us to tell beforehand that a given case is one of tumor of the pylorus which will terminate in a cancer? In my estimation there is no such possibility. There are no symptoms by which one may differentiate an eventually cancerous pylorus from one that will not become such. Two reasons for such belief are as follows:

1. Cases that terminate fatally may at the beginning give very slight symptoms, and, on the other hand, cases that are very mild may give very many serious symptoms.

2. Most pyloric tumors will become carcinomatous if given time and a chance. Out of thirteen pylorectomies performed by G. Faysse the microscopic examination showed ten malignant and three benign (*Archives Provinciales de Chirurgie*).

The subdivision of different tumors into inflammatory and neoplastic must in this case be ruled out for obvious reasons: Some of the tumors of the pylorus that are first inflammatory, such as hypertrophy, cicatrization, or an extension of an inflammation of an adjacent organ, may in time be converted into new growths or new growths be engrafted on them.

Considering that the occurrence of this disease is so frequent, and that conversion of an ulcer into a cancer is merely a question of time, we can readily see the importance of an early diagnosis. It certainly must be made at a stage when the degeneration has not yet occurred.

All symptoms in this disease differ only in degree. They are proportionate only to the amount of obstruction. The most so-called benign tumor will give the most malignant symptoms if it obstructs sufficiently the lumen of the pylorus. Brown says (*loc. cit.*): "Remember that in ulcer the total acidity is high, and free HCl is present in large amounts, whereas in cancer the total acidity is low, and free HCl is generally absent." He also insists upon a very careful analysis of the stomach contents. This classical symptom that so many like to associate with the presence or absence of cancer is also of no value, as we get cases with carcinomatous degeneration, with high, even very high acid, while some that are purely fibrous and non-degenerated with low, even very low acid. Not even the absence of a palpable tumor is of diagnostic value. Tumors may or may not be felt. In a well-built individual with a thick-walled abdomen a tumor may not be felt, though it be present.

Loss of weight, cachexia, and all other symptoms may be present and still the case may not be carcinomatous; and the opposite is also true—one may have a cancer and up to a late stage look very well. Pain as a symptom is also of doubtful value—it may and may not be present.

There is only one symptom that is of value, and the only one on which a diagnosis can be based, and when found the patient should be sent to the surgeon. I refer to the obtaining of food from a fasting stomach. No other symptom is of such value; no other symptom or group of symptoms is so invariably present. This symptom so often means pyloric obstruction, that other rare conditions where it may be present should be neglected. From the large number of gastric cases treated in the Department of Applied Therapeutics at the Vanderbilt Clinic I have picked out a few cases that illustrate these contentions very well.

Case I.—R., 63 years old, born in Russia, has always been a healthy man, very moderately alcoholic, drinks much tea, little coffee. He came to the Clinic on April 2, 1907, claiming that since February, 1907, he had felt heavy in his stomach, suffered from indigestion, vomited three or four hours after meals, the vomitus consisting of a sour, strongly smelling substance, *but never food remains.*

After vomiting he felt relieved; the appetite was good, he slept badly, and was constipated. He had lost considerable in weight and strength. At present the pain occurred mostly before meals, and after eating the pain was relieved. The patient was very weak. He was sent to a hospital, after having been treated at home, remained there two weeks, and was then discharged. The relatives were told that he had a cancer.

Examination shows him to be poorly nourished, much emaciated, pale, and weak. Heart negative; lungs emphysematous. Abdomen, no mass felt; liver and gall-bladder negative; slight tenderness on left side over colon. A meal of rice and raisins was given at night, and the contents of the stomach were removed in the morning. No food remains, mucus in excess, no lactic acid; total acidity 26; no HCl. A test breakfast was given and removed one hour later. The food was well broken up; mucus in excess; total acidity 50, hydrochloric acid 26; no lactic acid, no blood. Exploratory laparotomy was advised, and the operation was done a few days later by Dr. J. Blake. Nothing was found. The patient left the hospital weighing 119 pounds. Under treatment he began to improve, and at the end of July his weight was 141 pounds; he felt very well, ate and drank everything. He is perfectly well at present.

Case II.—T., born in U. S., aged 46, always well, moderately alcoholic. In 1907, without any previous symptoms, he began to have nausea and to spit up some blood. After that he was well until January 1, 1909, when he again felt nauseated, and spat up some blood and mucus. This has occurred several times since. Between the attacks he had almost constant sharp pain at the pit of the stomach and under the ribs, behind. The pain diminished after a meal, but returned about two hours later, and retained its sharpness until the next meal. There was no blood in the stools. He has lost 20 pounds since the spring, but is gaining again at present. Appetite fair, has eructations of gas and acid-tasting fluid. He has a good color, and is well built. Heart and lungs negative. Abdominal wall thick and fat, no masses felt, no tenderness anywhere.

January 5: The contents of the fasting stomach were removed at 10 A. M. The fluid contained a large amount of food remains and some free blood; total acidity 32, HCl 12; no lactic acid present; calves' liver eaten 16 hours previously constituted most of the food remains. Stool examined for occult blood gave positive results.

January 7: Examination of the fasting stomach, after a rice and raisin supper: 150 c.c. colorless fluid obtained, some rice and raisins, free blood toward the end; acidity 36, free HCl 26.

January 12: Examination of the fasting stomach showed Q.E. 5 c.c., clear fluid, no food remains. Diagnosis of pyloric obstruction made. The patient was sent to Roosevelt Hospital, when Dr. J. Blake operated upon him. A large pyloric tumor was found about two inches thick. The pylorus was removed and gastroenterostomy done. Patient recovered and is doing well.

Case III.—Mrs. H., born in England, 40 years old, was seen in private practice on August 19, 1908, just after she had taken two Seidlitz powders. Very pale, emaciated, and much depressed; she complained of great pain in stomach, and vomited everything she took. On examination the abdomen was found to be greatly distended, the stomach being very large, extending from the ensiform cartilage to two inches below the navel. A round, hard mass was felt at the pylorus. She was told to come to the Vanderbilt Clinic in the morning, fasting, having taken rice and raisins before retiring. Next morning removal of the contents of the fasting stomach showed 700 c.c. of a dark brown fluid, rice and raisins and food remains present, also blood; total acidity 74, free HCl 46. A test breakfast was given and removed one hour later. The food was well broken up, blood free, and bloody mucus and tissue were found. On further examination of the abdomen, a small tender lump was found, two inches to the right of the navel, through which, or just above which, a vibratory gurgle was heard. Liver border could be felt; the stomach was traced by percussion, three inches below the navel, the upper border being one-half inch above. The patient had lost, she claimed, about 50 pounds, and was very weak. A diagnosis of pyloric obstruction was made. She went to Roosevelt Hospital; Dr. G. Brewer operated and found a large pyloric tumor. This was removed, and also a large portion of the stomach. A gastroenterostomy was performed. On pathological examination a small area of carcinomatous tissue was found. At present the patient has regained all her weight and strength, feels very well, and eats and drinks everything.

On further examination of the records it was found that twelve months previously the patient had been in the clinic, complaining at that time that, for the last three months, she vomited after each meal—vomitus very acid. She had acute pain in abdomen, had sometimes to double up with pain; she had been very yellow at one time, and the stools were very light in color. She had lost 30 pounds in three months. A diagnosis of pyloric obstruction was made, and the patient was allowed to go.

Case IV.—S., 50 years old, German, good habits, never a hard drinker, came to the clinic in September, 1904, complaining that for the last three years he had vomited after eating, at first once a day, then more often, and for the last year he had noticed that he vomited food ingested a day or two before. At present he vomits only once a day, at 5 P. M., usually in large quantities. The appetite is fair, bowels constipated. He has considerable distress before vomiting, but no great pain except when he lies on the right side. Has lost 50 pounds in two and a half years. He is emaciated, heart normal, lungs emphysematous. There is a mass in the right upper quadrant of the abdomen the size of an orange, hard, not fixed, of uneven surface, and somewhat tender. Test breakfast removed one hour later: Food well broken up, pieces of raisin and seeds found (were eaten four days previously), also watermelon seeds eaten two days before, pieces of potatoes and vegetables. Total acidity 65, free HCl 25, some mucus, no lactic acid. Removal of the contents of the fasting stomach showed 76 c.c. of a fluid of brown purple color, some raisin seeds, eaten nine days previously. On further physical examination it was found that when the stomach was empty the pylorus could be felt above the navel, freely movable and tender. On percussion the stomach was traced up to the navel. The pylorus was two inches long and one and one-quarter inches wide, intermittently contracting and visible. Peristalsis was visible when the stomach was inflated. Another test breakfast was given and, removed one hour later, showed acidity 64, free HCl 22, no organic acid or blood. A diag-

nosis of pyloric obstruction was made. The patient was sent to Roosevelt Hospital and operated on by Dr. Hotchkiss. A cancerous tumor, the size of a fist, was found; several neighboring glands were involved. The tumor and about one-third of the stomach were removed. A posterior gastroenterostomy was performed. In hospital one test meal was obtained after lavage; no free HCl was found, lactic acid was present, and Boas-Oppler bacillus was found.

In case of R., all the symptoms of cancer were present, except the cardinal one, *retention of food*, and at operation no cancer was found. In the other three cases we see that the only constant symptom present in all of them was retention. In the last two tumors were felt. In the case of T. no tumor was found on examination, but a diagnosis was made in spite of the fact, on the retention of food alone. The tumor had not undergone any degeneration as yet, and after several washings the patient improved, and the fasting stomach contents were almost normal. But the man was intelligent enough to submit to an operation, and the result was that he was saved from the unfortunate condition of Mrs. H. and fatal condition of S. Mrs. H., a year previously, presented the same symptoms as T., and if an operation had been performed, no cancerous degeneration would probably have been found. S. has passed beyond the condition of T. and Mrs. H., and reached the stage where the cancer has already been fully established.

It is interesting to note that the last patient did not complain of any pain. This fatal case best illustrates the importance of early diagnosis, and that mostly on one symptom, retention of food, in itself a sufficient cause to transfer a patient from the care of a physician to that of a surgeon.

Loss of weight, while of great importance, is only significant if associated with retention. R. suffered a great loss of weight and strength, but that was probably due to the dieting which the patient was put under by his physician and in the hospital. The presence or absence of free HCl was absolutely of no diagnostic value in these four cases.

COMPARATIVE CHART

	Mr. R.	Mr. T.	Mrs. H.	Mr. S.
Loss of weight	Great	Moderate	Great	Great.
Tumor before operation.	Not felt.	Not felt.	Felt.	Felt.
Tumor after operation.	Not found.	Found.	Found.	Found.
Character of tumor		Purely inflam'tory.	Partially cancer.	Cancer.
Vomiting	Yes	Yes.	Yes.	Yes.
Vomiting of food	No.	Yes.	Yes.	Yes.
Vomiting of blood	No.	Yes	No.	No.
Pain in abdomen	Little.	Sharp	Very great	No.
Fasting stomach	No food present.	Food present.	Food present.	Food present.
Blood in stomach contents.	Not present.	Present.	Present.	Not present.
Lactic acid	Not present.	Not present.	Not present.	Not present
Test breakfast: total acid.	50	32	74	65
Free HCl	26	12	46	25
Q. E. from fasting stomach.	20 c.c	120 c.c.	700 c.c.	70 c.c.

On looking over the accompanying chart, we must emphasize again the importance of retention of food as the only symptom of diagnostic value. In the three cases this symptom was present. In the first case, which turned out to be negative, it was absent. We can also readily see the fallacy of considering the amount of free HCl of any value. In T.'s case, which was not carcinomatous, we found free HCl 12, while in the two others, which were carcinomatous, we had found free HCl 46 and 25. The total acidity in the early case was 32, in the two late cases 74 and 65.

Another very important point worth noting is that not one case had lactic acid present. The most advanced case had no blood in the stomach contents and no pain. In the mildest case there was vomiting of blood; in the others not. Also in one case no tumor could be felt, while it was found at operation.

These few cases illustrate well that there are no symptoms that may be relied upon with safety and waited for to make an early diagnosis of pyloric obstruction. Also that none of the classical symptoms, such as absence of HCl or presence of organic acid or pain or any one of the symptoms long accepted, are of such value as the one symptom that is most neglected, namely, the obtaining of food from a fasting stomach. The following seems to me the best rule in these cases, in view of an early diagnosis: Remove the contents of the fasting stomach, and, if food remains are found after one or two washings—high acid or low acid—blood or no blood—pain or no pain—a laparotomy should be performed.

1789 Fulton Avenue.

A CASE OF TETANUS, WITH POINT OF INFECTION THE CAVITY OF A TOOTH.

By W. H. LUCKETT,

NEW YORK.

Tetanus has been reported following injuries to nearly every part of the human body. The wound may be so insignificant and microscopic that its presence is either forgotten or not known. Minute scratches, slight abrasions of skin, leech-bite and bee stings, prick of needle, even hypodermic needles have been reported as the wounds of entrance of the tetanus bacillus. The following case is reported, because a search of medical literature does not reveal its analogue, because of the importance of knowing that it is possible to have tetanus enter the body through a cavity in a tooth and emphasizing the necessity of the care of such teeth, calling attention to the dangers of picking, with indiscriminate implements, the teeth, and lastly because we have here an opportunity, with the assistance of a very excellent bacteriological examination, to diagnose properly a positive case of tetanus in which there is no external visible wound on the body save the cavity of a tooth.

M. H., 10 years of age, admitted to my service at the Harlem Hospital on February 22, 1905. Referred by Dr. Loucks. Family history: both parents living and well, no diathesis traceable. Previous history: had measles as an infant, no other illness, but has a tendency toward indigestion, has had slight growing pains. Is a nervous child, somewhat emotional, subject to toothache, and has a habit of picking the teeth with anything that comes to hand—a straw, a needle, or a pin.

Present illness: Began four days ago with slight swelling of the neck, which was a little stiff. She was able, however, to talk and eat. The next morning she could open her mouth but a very little, and by evening the trismus was pronounced. She com-

plains of headache and soreness of her teeth. She has not had any tonic or clonic convulsions of any part of her body. Her whole body is slightly spastic, but not sufficient to interfere with the patella reflex, which is very brisk and markedly exaggerated. She has had no food and but little sleep during this time, and is an object of distress, as her buccal secretions constantly dribble from the angles of her mouth. No history of any punctured wound is obtainable, the only trauma received lately being a blow on the vertex with a stick, which, however, the parent claims, left no mark.

Present Condition: Conscious, rational, fairly well developed and nourished, general convulsive movements. Eyes: increased secretions, slight nystagmus, ocular excursion fair, pupils equal, semidilated and reacting. Mucous membranes of fair color. Tongue: moist, slightly coated. Mouth: several carious teeth on lower jaw, profuse salivation, and considerable foaming at mouth; pharynx not examined, as jaws could not be sufficiently opened to admit of it. Heart: normal size and position, rapid and regular; no adventitious sounds. Arteries: normal. Pulse: full, moderate force, slight tension, rapid and regular. Lungs: normal chest, poor expansion, moderate respirations, slight dyspnea, fair fremitus and resonant note. Normal voice and breathing sounds; no adventitious sounds. Abdomen: slightly retracted, board-like rigidity, no mass nor tenderness, tympanitic note. Liver, spleen, and kidneys: normal. Skin: smooth, soft, fair color, dry and warm; no rash nor eruption. Bones and Joints: apparently no organic lesions, marked rigidity of jaws and spasticity of most joints. Muscles: tonic contracture of muscles of jaw and abdomen, irritability of most of other muscles. Lymph nodes: quite large submaxillary. Reflexes: exaggerated.

February 22: Patient very restless, vomited once during the day; clear fluid. Takes a little fluid by mouth, but no solids; jaws quite rigid, mouth closed, considerable salivation, abdomen remarkably rigid and board-like. 10 P. M.: Very restless this evening. Apparently unable to swallow, so put on nutritive enemata. February 23, A. M.: Had numerous clonic seizures during the night and one slight tonic convulsion about 1 A. M.; retained nutritive enémata fairly well, salivation very profuse. Had three severe convulsions about 10 A. M.

March 1: Taken to operating room, and three teeth (two bicuspids and a canine) removed. Jaws were so rigid that anesthetic was attempted, but patient immediately had a seizure which was very severe. Amyl nitrite was used to overcome it, and slowly quieted her, clearing up the marked cyanosis, but was followed in quick succession by three more convulsions, while on operating table. This being clearly a case of head tetanus, it had been our intentions to trephine and do a subdural injection, but the patient's condition, rapidly getting worse, precluded this, and we had to be content with a spinal puncture. About 22 c.c. of spinal fluid were withdrawn and 18 c.c. of tetanus antitoxin injected. The cavities caused by extracting teeth were swabbed out with tincture of iodine. Mouth washed with boric acid and myrrh solution, nourishment given per tube in mouth. Patient has had severe clonic contractions during the day, but was conscious mostly all of the time and apparently rational. After a severe spasm about 6 P. M., patient was very weak, breathing became stertorous and pulse imperceptible at wrist. She was carried along for nearly an hour by stimulation, when she had another tonic seizure, during which she died. During tonic spasm jaws became very hard set, abdomen distinctly board-like, rigidity considerable, marked opisthotonos, profuse salivation; then legs became rigid, and lastly arms. Breathing practically ceased, face became livid, and mucous membranes purple.

Urine: February 22, pale yellow, opaque, heavy, muddy sediment acid. Specific gravity, 1037; slight quantity of albumin present. Sugar negative: Amorphous urates, Leucocytes, and epithelial cylindroids present.

A diagnosis of tetanus having been made from the clinical picture, as there was no other visible wound on the body save the carious teeth, they were removed and placed in a sterilized container and submitted for examination to Dr. Leo Buerger, who reports the following: The material for examination consisted of two foul-smelling, dirty, necrotic teeth, the larger portion of a third tooth, together with a small, ragged tooth fragment. Spreads made from many parts of this material showed a multiplicity of bacteria, none of which could be identified as tetanus bacilli in the stained specimen. There were streptococci, staphylococci, Gram negative and Gram positive bacilli of the most diverse morphology, spirilla, and diplococci.

The bacteriological examination of the material was conducted as follows: First, by direct animal inoculation, and, secondly, by culture.

Animal Inoculations: A guinea pig, weighing 300 gm. received 0.5 c.c. of a saline suspension (made by shaking up all the material in 2 c.c. of sterile normal salt solution) subcutaneously in the right groin. The small, ragged fragment of tooth, above mentioned, was also inserted in a small pocket, under the skin, made a short distance above the point of inoculation. On the seventh day the right leg became spastic. On the eighth an occasional general body tremor could be observed. The spasticity of the limb was more marked, and the animal was quite sick. The stiffness of the limb persisted for four more days. There was suppuration at the site of inoculation, but the guinea pig recovered. Three weeks after the inoculation the wound was completely healed. White mouse No. 1 received 0.25 c.c. of the same suspension, subcutaneously in the right groin. No observation having been made during the nine to twelve hours before death, any tetanic symptoms which may have occurred during that period were not recorded. However, the animal died in seventy-two hours, the body being found markedly bent upon itself, an evidence apparently of convulsions before death. The autopsy on this mouse showed a foul-smelling abscess in the right groin. Spreads made from the pus of this abscess did not demonstrate the presence of any tetanus bacilli. Two loopfuls of this pus were emulsified in sterile salt solution and injected under the skin of right groin of another white mouse (No. 2). Mouse No. 2: Inoculated February 26, at 5 P. M., with the above-mentioned pus. On February 27, A. M., right leg spastic and extended. 2 P. M., right fore limb also spastic, with some rigidity of the whole right side of the body. 5 P. M., left side of the body becoming involved, first some rigidity of left hind limb; later of the left fore limb. 8 P. M., general convulsions. 10 P. M., killed by means of chloroform. Autopsy showed no macroscopic lesion.

Culture Experiments: A pure culture of typical tetanus bacilli was isolated from the emulsion made

by washing all the material in sterile normal salt solution. The methods of Kitasato were employed. The pathogenicity of the organism was determined in the following animal experiments:

White mouse No. 1 received 0.2 c.c. of a two days' culture of the tetanus bacilli in neutral broth at 10:30 A. M., February 28, 1905. The injection was made under the skin on the right groin. After eleven and a half hours the right hind limb became spastic. Then there followed a gradual involvement of the other extremities, with general convulsions and death in twenty-one and a half hours. Guinea pig No. 1, weighing 300 gm., received 0.25 of the same culture under the skin of the right groin. Death occurred in twenty-three and three-fourths hours. It was preceded first by stiffness of the right hind leg, then general extension of the spasticity, and finally convulsive movements.

Guinea pig No. 2, weighing 600 gm., received four loops of the same culture in the same region. The period of inoculation was two days. Then the typical symptoms set in, and death ensued at the end of three days and eleven hours. Mouse No. 2, injected in the same situation with one loop of the culture, died of tetanus in thirty-nine hours. By this work we have removed a positive case of tetanus from where it otherwise would have been assigned, *i. e.* the board, questionable field of so-called tetanus idiopathicus, and proven that it is possible to have an infection of the *Bacillus tetani* enter the human body through a cavity in a tooth.

IS CONGENITAL CATARACT CAUSED BY DYSTOCIA?

By GEORGE EDWARD BARNES, B.A., M.D.,

HERKIMER, N. Y.

I WISH to report a case of congenital cataract in the hope that the history of future cases may be more carefully investigated for the purpose of clearing up the causation. The patient was born less than five years ago. The labor (at which, by the way, I was not the accoucheur) was very long, and the head appeared in occipitoposterior presentation The child was slightly asphyxiated and was resuscitated none too well by hot and cold plunges. The cranium was much compressed. The child was perfectly formed, but he weighed only 5½ pounds. During the first month he was not at all well, was emaciated, and had a few mild convulsions. Nothing unusual was noticed about his eyes until after a week or longer. Then the pupils were observed to be slightly gray. There were also internal strabismus and general nystagmus, caused probably by the presence of the cataracts. The gray color of the pupils gradually became lighter. The case has been treated by oculists by several discissions which have removed the lenses with the exception of small segments on their equators.

The child has never had any constitutional disease. As soon as the brain pressure symptoms disappeared, *i. e.* after the first month, he gained very rapidly in weight. He is as observing as a child with his eyes can be. Mentally he has been very alert and bright, as evidenced by his ability at the age of 3½ years to recite from memory long selections of verse.

Concerning this case there is the interesting question whether the cataracts were caused by injuries sustained during dystocia. It seems more than probable. May it not be that the moulding of the head by the great and prolonged pressure so increased the intraocular tension that the lenses were repeatedly forced along the line of least resistance forward and, with the irides, into the anterior chambers, the result being that the suspensory ligaments or capsules were so injured that the lenses did not continue to receive their lymphatic nutrition and became opaque?

AN IRRIGATING STONE-SEARCHER.*

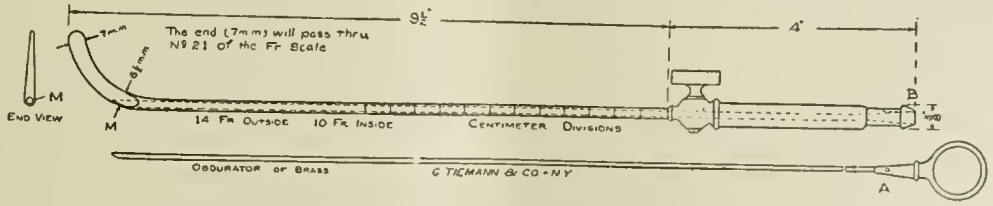
By VICTOR COX PEDERSEN, A.M., M.D.,

NEW YORK.

GENITOURINARY SURGEON OF THE OUTPATIENT DEPARTMENT OF THE NEW YORK HOSPITAL AND HOUSE OF RELIEF (HUDSON STREET HOSPITAL).

No one to-day with experience in cystoscopy would think of using a stone-searcher instead of the cystoscope for diagnosis. Nevertheless, there are many physicians who meet lesions of the bladder, particularly in the form of various calculi, who have no cystoscope or are not momentarily in surroundings which permit the use of one. Moreover, certain elements of prostatic conditions are very conveniently diagnosed and measured with the stone-searcher. consequently the instrument holds an important position still in the instrument-cabinet of surgeons and specialists. It is desired to call attention to the following modification of the irrigating stone-searcher of Posner, or more properly speaking to the following combination of the Thompson nonirrigating and the Posner irrigating stone-searchers with certain additional changes.

First, a brief review of the Posner instrument will be worth while. Its point was olivary, its curve on the radius of that of the standard sound, but shortened by about an inch, without, however, any flattening whatever from side to side; its shaft was approximately 14 French outside diameter, and about 9½ inches long, including the curve. It ended in a stop cock followed by the handle and nipple for the hose-connection; a canal passed from the nipple to the curve, where it ended well up toward the point in such a way that the tube is not a straight line from end to end and cannot be easily cleansed nor fully closed with a full-sized obturator, but rather with a rather fine wire. From the stop cock toward the curve for about the half-length of the shaft, centimeter graduations were cut, and a rider placed for marking the measure as needed.



Second, a few words on the model of the Thompson instrument should not be omitted. It is of the nonirrigating type, with the curve flattened from side to side, and of size to pass through 24 French,

*Exhibited at the Genitourinary Section of the New York Academy of Medicine, October 20, 1909.

but tapering rather suddenly to the size of the shaft, commonly about 12 French; this results in what the writer considers a defect in this instrument, namely, a sort of spatula-shaped tip, too wide near the point, and too narrow near the shaft, so that a small stone lying near the shaft might be readily overlooked. The other features of the Thompson instrument need no note here.

The illustration shows the stone-searcher of the writer concerning which the following points may be noticed: Its curve is on the radius of that of the standard sound, shortened by one inch and flattened from side to side throughout its length from extremity to shaft. Its extreme width will pass through 21 French, and is reduced only from 7 to 6½ mm., where it joins the shaft. The diagram shows this well in the end-view and side-view of the instrument. The shaft with the curve is 9½ inches long, and duplicates the Posner instrument, with these exceptions: *a* There is no rider for the scale of centimeter graduations. *b* (Most important of all) a 10 French silver catheter passes from the base of the curve to the hose-connection in the handle in one straight line, thus giving to the instrument all of the advantages of the same plan laid down for the writer's "Irrigating Sound of the Standard and Beniqué Type," described in the *Annals of Surgery*, for October, 1909. The obturator of the stone-searcher is a full-size brass wire, which passes through to the opening of the catheter at the base of the curve (see M. of the cut). At this point it is convexed, while the catheter is concaved, in order to correct any sharp edges or corners.

The tube-connection (B) receives 3-8-inch diameter rubber tubing and seats the obturator in a modified bayonet-catch. The slot of this catch and the plug (A) of the obturator sitting into the slot are so arranged that the sharp oblique point of the obturator cannot possibly be exposed at M through the tube. This detail adds safety in the use of the instrument.

The advantages for this instrument are, that it may be used either for an irrigating or nonirrigating searcher, that its flat beak permits diagnosis of small stones with greater certainty, that its straight large tube permits of rapid and full irrigation of the bladder when required, and also much more adequate cleansing and asepsis of the instrument.

From the experience of the writer with it, it is warmly recommended to those requiring an instrument which combines and improves the good features of the Posner and the Thompson instruments.

45 West Ninth Street.

Contagion and Semiology of Scarlatina.—A. Lesage makes a very forcible and convincing plea for the noncontagiousness of scarlatina during desquamation. He bases his diagnosis of scarlatina on the evolutive cycle of the tongue and throat. Here we have a cycle which goes on for about fifteen days. First redness, then white pultaceous covering, then strawberry tongue and red throat, then clearing up of both. Here we have a cultural cycle. After it is finished we have no longer contagion. Desquamation is a mere serum phenomenon resulting from a toxic eruption, and the scales are not contagious. Children inoculated by hypodermic with mucus from the throat all took the disease, while those inoculated with the scales did not. There are many cases of scarlatina without eruption, and these are just as virulent as those in which the symptom is present. Diagnosis based on an adventitious circumstance is incorrect, and this is the cause of the spread of the disease. The diagnosis should be based on the condition of the mouth and throat alone. Quarantine should end with the end of the throat and tongue cycle. Exclusion from school should be based on the condition of the throat and tongue, not of the skin.—*Gazette des Hôpitaux.*

Congenital Stricture of the Urethra.—Gallois says that congenital stricture of the urethra is rare. It is due to the fact that the urethra is developed in three separate portions derived from different structures; the posterior urethra is developed from the cloaca, the middle portion from the urogenital sinus, the anterior portion from the balanic layer. If these portions do not adhere perfectly or the lumen is not entirely hollowed out there is an opportunity for the development of stricture. The lesion found anatomically is a subepithelial sclerosis, there being no changes in the mucosa. The stricture may appear acutely, or be preceded by a period of imperfect urination, frequent, with small stream, and slow. This is followed by acute retention or incontinence. The sound shows the existence of a stricture.—*Le Nord Médical.*

Surgical Operation on the Hypophysis in a Case of Acromegaly.—P. Lecéne describes an operation for a tumor of the hypophysis performed for the relief of acromegaly by the transsphenoidal route. The patient was a typical case of acromegaly, with partial blindness and epileptic crises. A tumor of the hypophysis was diagnosticated and operation was done by opening the nose, passing through ethmoidal and sphenoidal cells into the sella turcica, and the removal of a considerable amount of tissue from the hypophysis. The patient lived some six weeks after the operation, the external wounds entirely healed, but he died suddenly. An examination of the skull and brain after death showed that the tumor of the hypophysis was an epithelioma with several prolongations into other parts of the skull and around the cavernous sinus. It was entirely unencapsulated, and could not have been removed by the route taken or any other. The author believes that it is not justifiable to operate by this route, because there is not room enough to reach the region of the sella turcica, and it is impossible to see and to tell what the operator is doing; it is surgery in the dark, and therefore unsurgical. There is also the danger of infection by way of the nasal fossæ which communicate with the wound. The author does not believe in the theory which makes acromegaly the result of increase of function of the pituitary gland. It is more likely to be from insufficient function of that gland in cases of tumors taking the place of the gland. The idea of removing a portion of an adenoma of the hypophysis to remedy an excess of function of the gland is based on small and fragile hypothetical considerations. It is experimentation upon the living. It is impossible to know the limits of the tumor.—*La Presse Médicale.*

Dystocia Due to the Cord.—Henri Bertier says that the umbilical cord can be the cause of delayed labor on account of its anatomical structure, by being too short or too long. A short cord may be so short as to constitute a true adhesion of the fetus to the placenta, in which case the two must be delivered together. A marginal insertion of the cord or of the placenta will cause dystocia. There may be adhesions of the cord to fetus or placenta. A short cord cannot be diagnosed before labor; often it is only discovered to exist after delivery. The patient complains of a fixed pain situated at the upper lateral portion of the uterus. The contractions are short and irregular. Labor is long, dilatation bad, and pain severe. When the placenta is separated hemorrhage is severe. Uterine inversion may even be produced by traction of the fetus on the cord. The cord may be ruptured during the descent of the fetus. Short cord favors the deflexion of the head and shoulder, or breach presentation. Another form of defect is constituted by the winding of the cord about the fetus. This may cause intrauterine amputations, or strangulation of the fetus. Forceps operations are often necessitated to deliver the child. The fetus will often compress the cord during its descent. Before labor loose loops of cord are most dangerous, but after labor has begun tight ones are most to be feared. Pressure on the vessels of the cord causes stasis of circulation or anemia of the bulbs and cerebral centers. A third complication is procidentia of the cord, resulting in pressure on it by the fetus. The most important etiological factors are narrowing of the pelvis and low insertion of the placenta. Pinard includes both under failure of accommodation of the labor by the pelvis. As to treatment, it seems to be of little use to try to replace the cord, since it is almost impossible to keep it up. A balloon may be used to keep it in place and to dilate at the same time. According to some, when the cord is irreducible, whatever the amount of disproportion between fetus and pelvis, a cesarean section should be done at once. When it is reducible, but the pelvis is contracted, a cesarean done early is to be preferred to a late symphyseotomy.—*Gazette des Hôpitaux.*

THE INCREASED COST OF LIVING IN RELATION TO RACIAL DETERIORATION.

BESIDE the unfavorable influence which the present increased cost of living may be expected to exert upon the rates for sickness and death, as previously touched upon in these columns, its profound ultimate effect upon the future of the race and nation cannot be disregarded. It is quite true that, in the public mind at least, our chief purpose as physicians is to heal the sick. This, however, is quite far from being the case. More properly, our first duty is to prevent disease—then, when our efforts fail of completeness, to endeavor to remedy what was not prevented. More than this, our obligations in this respect extend, as physicians, to the generations yet unborn, and, as citizens, to the welfare of the Republic of the future. As medical men, we cannot salve an easy conscience with the cynical conclusion that, as posterity has done nothing for us, there is no reason why we should do anything for posterity. We must consider the living generations of to-day not only as individual patients but as the ancestors of to-morrow, whose present physical condition will be faithfully reflected in the physical standards of later generations of descendants. In this, we are simply applying to the human animal the common knowledge of stock raisers, who have learned through long experience the controlling influence which heredity, nutrition, and environment exert on size, strength, appearance, and character.

Nor are the precautionary measures, which the welfare of future American citizens demands, necessarily medical. On the contrary, they very largely relate to industrial and economic improvements, which are most surely and promptly secured when we temporarily lay aside the medicine case and scalpel and unite as a profession to lead the public at large toward betterment in the general welfare. To do this to best advantage, we must rise above the unduly narrow medical view which simply considers the bringing of relief to the ailing human unit. This latter is of course essential, but is frequently mere temporizing which does not reach and remove the original predisposing or controlling causes of disease, suffering, and defectiveness. In the dual capacity of physician and citizen, the overlapping domains of preventive medicine and sociology lie open to us, and there is almost no limit to the improvements which as a profession we can bring about if we once fully appreciate our dual responsibilities. The medical profession is recognized as being an unselfish element in the community which constantly works against its own advantage—hence politics and special interests are always as surely afraid openly to oppose the disinterested humanitarianism of the doctors as it is certain that the general public will ultimately rally to their successful support. And there can be no greater service which can be done for humanity and the future of the nation than in promoting such conditions for the present generation as will favor the transmission of strong bodies and sound minds to its posterity.

There can be no doubt that present economic and industrial conditions are tending to rapid deterioration of the race throughout the world. A young, vigorous, undeveloped nation ourselves, whose life blood is constantly freshened by a sturdy class of immigrants, such tendency is not yet as apparent with us as with the older nations, where greater congestion and fiercer competition are rapidly bringing about decadence. Yet if existing conditions in this country are to be allowed to prevail, such deterioration is undoubtedly inevitable for us, even if delayed, and it behooves us to look ahead and take preventive measures for the future accordingly. Nor does the situation admit of delay. Great Britain is to-day confronted by a not only numerically great but steadily increasing class of physical, mental, and moral defectives of her own producing, who have in turn created problems in sociology, criminology, and public health which threaten her very national existence. It is stated that the average British recruit for the Crimean War, when England contained a large class of well-fed sturdy yeomanry, was nearly three inches taller and nearly thirty pounds heavier than the average recruit for the Boer War, two generations later, when an undernourished, degenerate population, four out of five of which lived in cities, was found to have developed. And before the end of the latter war, in which only about 250,000 soldiers out of a population of some 35,000,000 were required, the recruiting officers had to accept as soldiers adult males only five feet tall, in spite of the fact that such undersized racial degenerates were fully recognized as lacking not only in physical strength but also in constitutional stamina and mental ballast. Statistics for the year 1906 show that the height of the average British infantry recruit for that year was 64½ inches, his weight was 123 lbs., and his chest measure was 33 inches. When we compare this stunted development with Sargent's actual averages for youthful American college students, of 68 inches height, 139 lbs. weight, and 36.3 inches chest measure, we can appreciate that the days of the sturdy English "beef eater" are gone, and that Kipling's reference to the "thin red line of 'eroes" has more applications than one. Even the German government, which requires thorough physical training in schools and gives great attention to the maintenance of a high standard of living in the industrial classes, finds a steadily decreasing percentage of German conscripts able to conform to army physical standards. Its investigations have

demonstrated the fact that the larger the town the greater the proportion of male inhabitants unfit for military service, and that this unfitness materially increases with the second generation.

On our part, we must not forget that in 1800 only 4 per cent. of American citizens lived in towns, while in 1900 the proportion of city dwellers was 30 per cent. Under the then more primitive conditions of life, at least an abundance of nourishment was within reach of all; but at the present time the cost of living has forced the large class whose wages have not proportionately advanced to give up the more expensive nutritious foods which they were formerly able to procure. Even organized labor, with its more generous wages, has largely joined the present meat boycott; and it is a sad commentary on existing conditions, which it will take more than political sophistry to explain, that a large part of the body politic must deprive itself of an essential article of nourishment in order to struggle more effectively against economic conditions rapidly becoming intolerable. If it cannot justly be claimed that a large part of the American population is as yet suffering from chronic malnutrition—as is the case with the British masses—still it can be safely asserted that our poorer classes are already practically on its verge. It can also be safely asserted that if present conditions are allowed to persist, the cost of living must continue to rise and the financial extremes of society became more and more widely separated. And as medical men we cannot afford to remain blind to all but the practice of medicine and surgery while remediable causes are allowed to create in this country a "submerged tenth," in whom want, misery, and insanitation will inevitably breed descendants degenerate from the physical, mental, and moral standpoints alike. No one appreciates like the physician how the incidence of disease and recovery therefrom are largely dependent on ability to secure the reasonable comforts of life. Our hospitals, asylums, and penal institutions are chiefly filled from the class of the impoverished, which by its very helplessness and degeneracy retaliates upon society at large for permitting conditions under which such human derelicts are largely produced.

To the medical profession as a whole, public opinion entrusts the welfare of the race, and through this welfare, the destiny of the nation, not only for the present but for the future. Let us not overlook the fact that many of its undoubted physical ills—causes of disease and death—find their origin in deep seated economic, industrial, and political conditions quite beyond the reach of drug or knife. Proper attention by us to such present conditions will have a profound effect in reducing the gravity of the problems which the physician, sociologist, and statesman of the future will be called upon to solve. The reasonable well-being of all classes of citizens is a matter of fundamental medical importance which cannot be eliminated from any consideration of the physical future of the race. Such general welfare is favored by conditions which bring the greatest good to the greatest number; not by those which pile up excessive wealth for the few and increase the difficulties of actual existence for the many. There is both truth and poetry in Goldsmith's lines:

"Ill fares the land, to hastening ills a prey,
Where wealth accumulates, and men decay."

HUMAN DERELICTS.

A CERTAIN amount of public interest, or at least of newspaper notoriety, has been aroused by a recent address delivered by Professor W. T. Porter of Harvard University upon the subject of public charities. Speaking from the point of view of the economist, Dr. Porter stated that for the greatest good to the greatest number the system of individual charity to the old and incompetent was to the detriment of the race and that those who are incurably ill or incapable of self support should be passed by in the distribution of alms and only to those for whom there is a reasonable hope of recovery should aid be given. To quote Dr. Porter's own words, as reported in the New York *Sun* for February 13, he said in part: "The most pressing problem is what we shall make of the present conditions. The first main problem we have to discover is in regard to the relieving of distress. It is evident that there is not enough money to go around. And it is equally desirable to spend money on a thing from which we get the most value. . . . It may seem cruel, but . . . we must concentrate our relief on the most hopeful side of our population and allow the rest to go the way of nature. . . . The whole question is one of economy. It is a mistaken idea to believe that everything depends on charity for the old and not on prevention for the young. Charity means that those who receive it give up hope. Charity is the gravest psychological factor in the life of the poor. It is an official stigma. Instead of organizations for charity there should be a citizens union for preventing charity. When a person gets to that point where he is physically unfit to live the most economical thing for a community is not to give him relief."

The carrying out of such Spartan principles may be, from the viewpoint of race culture, wholly desirable. The derelict hulk at sea is abandoned and the money which might be used in repairing its rotten frame is spent upon newer, stauncher vessels, and a more useful navy results. There are, however, certain serious objections to these theories propounded by Dr. Porter. In the first place, while the idea may represent the economic aspect of the question, it entirely omits the element of personal sympathy. While it is comparatively easy to lay down the rule from the office of an organized charitable institution or the lecture platform of a great university, that the old and decrepit shall be abandoned, the average human being on coming in contact with a suffering old man, in his palmier days possibly a most worthy man, but broken down by disease and hardship, can hardly be expected to moralize on the advantage of reserving the few pennies needed and devoting them to puericulture, and of allowing the present sufferer to starve. The first definition of the word "charity" given in Webster's Dictionary is "love," the second is "universal benevolence," and the third is "good will." As long

as humanity exists the idea of charity will be associated with that of love, and the personal love will ever outweigh the general impersonal economic charity which says that the survival of the fittest must be obtained by the abandonment of the unfit.

Overlooking, however, the element of personal sympathy and considering only that of the good of the race, it is questionable whether the abandonment of the diseased and helpless would achieve the results for which Dr. Porter apparently hopes. He refers in his address to the case of tuberculosis and says that for one case saved by institutional treatment five must be rejected because the hope of cure is too small to make their treatment economically worth while. He completely ignores the fact that each of these cases so neglected and allowed to roam at large is adding an extra danger to the community. The modern ideas on the prevention of tuberculosis are tending more and more to the principle of segregation of the helpless and the hopeless, and less to the care of the incipient. The ruthless abandonment of the chronically diseased would tend but to the spread of infection and the increase of misery. It were far better for the human race should fewer children grow to manhood, and these in surroundings free from disease than for a greater number of weaklings to be nurtured and bolstered past the early critical period of their life, only to grow to manhood associating freely with the contaminated and the diseased, neglected and at large. To return to the metaphor of the ship, the useless derelict, though it may not be worth repairing, if not sunk outright must be towed into some safe harbor, and not be abandoned to drift on the high seas an ever-present menace to navigation.

The Early Case.

Mr. John R. Early, and incidentally the general public, will begin to have a pretty poor opinion of medical diagnosis as an exact science if he is submitted to many more examinations. First he was declared a leper by the health officer of Washington and was imprisoned for the crime. After some time his case was brought to the notice of Dr. Bulkley of this city, who examined him and declared there were no signs of leprosy. With great difficulty the prisoner obtained his release and came to New York, where he was again pronounced free from all taint of the disease. In the mean time a piece of the man's skin was sent to Bergen and was there examined by Hansen, who found what he thought was a lepra bacillus, and on the strength of this find pronounced Early a leper. The War Department said he was not a leper and accordingly cut off his pension. He went to Washington to inquire about it and was arrested and again incarcerated on the charge of being a leper. After much trouble he was once more released and came to New York in a freight car, the railway officials fearing he might endanger the health of the syphilitics, the tuberculous, the carriers of typhoid and diphtheria bacilli, and other infection-spreaders in the Pullmans. Here he was presented to the Society of Medical Jurisprudence, and a committee was appointed to examine him again. This committee reported that he had an anesthetic spot on the leg and that an acid-fast bacillus was found in a piece of his skin, and so declared him a leper. The Society was becomingly and, in view of the fact that it is composed of lawyers and physicians, astonishingly modest and refused to pronounce on the matter, but simply accepted the report of the committee and discharged the latter. In the mean time five well-known neurologists examined the man and reported that they found no evidence in skin or nerves of anesthetic leprosy, and no one accuses him of having tubercular leprosy. And Dr. Bulkley remains steadfast in his opinion that Early is not a leper. With this opinion most onlookers who have not seen the man and who have only the testimony of the various examining committees and individuals to guide them will agree. The only evidence of a positive nature that has been given is that the man when first seen had a skin eruption, that an acid-fast bacillus has been seen in a section of his skin, and that there is a small patch of slight thermic and tactile hypesthesia on the leg just above the ankle. The eruption has entirely disappeared, the acid-fast bacillus might be one of half a dozen different microorganisms, and the hypesthetic area is no more than any one might have, and many healthy persons do have. There are no signs of tubercular leprosy, no thickening of the nerves, and no skin eruption now, although the man was declared a leper two years ago. The community punishes lepers more severely than it does most murderers, but murderers would not need to invoke a brain storm in their defence if no more convincing evidence were brought against them than has been brought against poor Early. He is a leper and not a leper. He is prevented from earning a living in peace because he is a leper, and his pension has been cut off because he is not a leper.

The Study of Pellagra.

It has been announced recently that a committee has been formed in London, the membership of which includes the Italian Ambassador, the Marquis of San Guilliano, Sir Thomas Clifford Allbutt, regius professor of physic in Cambridge University, and a number of prominent scientists and physicians, to promote the investigation and study of pellagra. The British Colonial Office has also contributed toward the carrying out of this project. It is proposed to send Dr. Sambon of the London School of Tropical Medicine, who has made a close study of the disease, together with a qualified staff, to a pellagrous area, to investigate the conditions and the various blood-sucking flies by which he thinks the disease is disseminated. Dr. Sambon holds the view that pellagra is protozoan in its origin, like sleeping sickness, and many skilful observers are said to be favorable to his opinions. It is only within the past year or so that the existence of pellagra on a wide scale has been recognized generally in this country. Now, however, it has been established clearly that pellagra is prevalent in certain parts of the United States and that the disease is increasing. Pellagra, or as the Spaniards first termed it, the disease of misery, is emphatically a disease of the very poor. For long, in Italy and in other lands in which the malady exists on a large scale, its origin and dissemination have been attributed to the ingestion of unripe, or mouldy, musty corn. On the face of it this theory has much in its favor. In Italy, in fact, in all lands in which pellagra is rife, the disease follows, or at any rate seems to follow, the ingestion of maize in bad condition. The Italian

authorities are so convinced of the validity of this view that in Italy the law makes pellagra a notifiable disease, prohibits the sale of bad maize, and makes compulsory on local authorities the construction of drying houses for maize. Furthermore, the carrying into effect of these regulations has decreased the prevalence of the disease. However, although many things seem to point to maize unfit for human food as the *fons et origo* of pellagra, it may, after all, be but a contributory cause. It is yet within the remembrance of the present generation that malaria was opined to be caused by ground exhalations, and it was a considerable time before its dissemination by the mosquito was generally conceded. Since then, however, the transmission of disease by insects has been shown to be remarkably frequent, and it would be rash at present to deny the possibility of such transmission in the case of pellagra.

The Treatment of Meningococcus Carriers.

As the result of recent investigations into the epidemiology of cerebrospinal meningitis the belief has steadily gained ground that one of the most important modes of transmission of the disease is by healthy meningococcus carriers. It has been demonstrated in many instances that the organism in a highly virulent state may be isolated from the nasal secretions of a considerable proportion of persons who have recently come in contact with sufferers from the disease. Various methods have been suggested to overcome the danger arising from the free intercourse of these infected individuals with their healthy and possibly susceptible fellows. Isolation of all those exposed has been suggested, but has not been very generally enforced; and the many efforts which have been made to kill the organism in the nose of the carriers have, up to the present, been of but small avail. In the *Deutsche medizinische Wochenschrift* for January 13, 1910, however, Hans Bethge reports an investigation which offers some hope that this intranasal disinfection may be accomplished. Last spring an epidemic of meningitis, involving nine children, occurred in an orphan asylum in Gelsenkirchen, and every inmate of the institute was examined for the presence of meningococci in the nose and nasopharynx. Of the 187 persons investigated 60 gave positive results. These were isolated and treated by various methods with the result that it was shown that a one-per cent. solution of hydrogen peroxide is a most efficient antiseptic for the meningococcus in the nose. The author believes that his success in killing the meningococcus with this drug, with which others have failed, depends upon the fact that previous to its application he irrigated the nostrils gently but thoroughly with a one-per cent. salt solution. This, by removing the large masses of mucus, under which the meningococcus might lie hidden and protected, enabled the peroxide to act upon the entire surface of the mucous membrane. In 60 per cent. of the carriers, one such treatment completely killed off all of the meningococci, and in the remaining 40 per cent. a few repetitions of the application brought about the desired results. If this work is confirmed, and it is proven that such a simple procedure renders the meningococcus carriers innocuous, it should be adopted as a routine measure in combating the spread of epidemic meningitis.

News of the Week.

Italian Antituberculosis Committee.—A committee has recently been formed in New York composed of the leading Italian citizens and under the chairmanship of Mr. Lloyd C. Griscom, former Ambassador to Italy, the function of which will be more effectually to carry the antituberculosis campaign to the inhabitants of the Italian quarters of the city. According to the statement published recently: "This committee plans to divide the Italian colony into districts, disseminate information concerning tuberculosis through circulars and pamphlets, and, through the distribution of the very attractive Venetian poster, notify the Italians in each district of the location of the nearest tuberculosis clinic. This committee expects to undertake a campaign for the better ventilation of the homes and workshops of the people; to furnish weekly press service to the Italian newspapers; to establish lectures, illustrated with stereopticon slides, before the Italian churches, clubs, and labor organizations; to hold tuberculosis exhibitions in the heart of the Italian colony; to pursue investigation into the peculiar needs of the Italian tuberculous poor; the establishment of special clinics, and the appointment of Italian physicians and nurses."

Leprosy Scare in Chicago.—During the last few weeks a rumor has prevailed in Chicago to the effect that leprosy was present in the city, and that it was introduced and spread by the medium of artificial hair imported from Oriental countries. Various attempts to trace the reports to their source have failed completely, nothing more definite than "hearsay" reports being obtainable.

Sales of Antitoxin to Be Reported.—An ordinance passed by the City Council of Chicago recently requires all persons, firms, or corporations to report to the Commissioner of Health within twenty-four hours any sale or gift of diphtheria antitoxin within the City of Chicago. The penalty for failure to comply with this ordinance is a fine of not less than five or more than fifty dollars for each offense.

The United States Pharmacopeial Convention.—The second call for the convention for the revision of the United States Pharmacopeia has been issued. The notification and credential blanks adopted by the Committee on Credentials and Arrangements have been mailed to all organizations and institutions supposed to be eligible to representation, in so far as they are known to the secretary. Notification of the appointment of delegates should be forwarded at once to the secretary, who will, upon application, furnish these blanks to any organization or institution entitled to them. By vote of the Board of Trustees three amendments to the constitution will be offered. The membership will be increased by admitting delegates appointed by "the Secretary of Agriculture, the Secretary of Commerce and Labor, the Association of Official Agricultural Chemists, the Association of State and National Food and Dairy Department, the National Wholesale Druggists' Association, and the National Dental Association." The number of delegates which each organization is entitled to send is to be reduced from three to one. The title of the "Committee of Revision" is to be changed to that of the General Committee of Revision. The following proposition to amend the by-laws will also be submitted:—To increase the number of members on the Committee of Revision, hereafter to be known as the "General Committee

of Revision," from twenty-five to fifty, said General Committee of Revision to create from its own membership an Executive Committee of Revision of fifteen members, to have immediate charge of the work of revision, and also giving to said General Committee of Revision certain advisory and supervisory powers over the work of the Executive Committee of Revision.

Smallpox in Lima, Ohio.—The State Board of Health Examiner of Ohio, who has recently visited Lima to inspect the smallpox situation in that city, has reported the existence of 200 cases, 15 of them serious.

The State Board of Health of Oklahoma has recently opened an office in Oklahoma City, having moved to that city from Shawnee.

Amalgamation of Medical Societies in Milwaukee Planned.—An amalgamation of the Milwaukee Medical Society and the Milwaukee County Medical Association may be effected within a short time. At a meeting of committees representing the two organizations Monday night, it was decided that the library owned by the Milwaukee Medical Society shall become the joint property of both organizations.

Mt. Sinai Dinner.—The Annual Dinner of the Associated Alumni of Mt. Sinai Hospital will be held at the Hotel Knickerbocker, on February 26, 1910. On this occasion the Association will commemorate the fiftieth anniversary of Dr. Abraham Jacobi's connection with the hospital.

Dr. E. P. Busse has been appointed superintendent of the new Southeastern Hospital for the Insane being built at Madison, Ind.

Charitable Bequest.—By the will of the late Belden R. McAlpine of New York the New York Society for the Relief of the Ruptured and Crippled is made one of the residuary legatees. It is believed that the society's share of the estate will amount to about $50,000.

Colleges Asked to Teach Optometry.—Optometrists have asked Columbia and New York Universities to establish departments in which young men may study the science of testing eyes for errors of vision and prescribing and fitting eye glasses. The men in the movement say that although an optometry law has been in effect in the State for two years, New York City has no school in which candidates can qualify to take the examinations given under the law's provisions.

Dentistry for Schools.—Senator T. J. McManus has introduced a bill into the State Senate at Albany to amend the charter of New York City by requiring the Board of Health to establish and maintain dental stations for children up to the age of fourteen years, attending any school in the city, who are unable to pay for treatment. He says the bill is introduced as a result of the complaint of doctors in New York who declare that on account of neglected teeth there are many cases of illness among the school children.

The German Society for Surgery.—The thirty-ninth congress of this association will be held in Berlin beginning Wednesday morning, March 30, 1910, and lasting until Saturday, April 2, 1910 in the Langenbeckhaus. Ziegelstrasse 10-11, under the chairmanship of Professor S. Bier. Membership cards and information may be obtained from Herr Melzer, Langenbeckhaus, Berlin.

The Harvey Society.—The sixth lecture of the Harvey Society will be delivered by Dr. Eugene L. Opie of the Rockefeller Institute for Medical Research, on Saturday, February 19, 1910, at 8.30 P. M., at the Academy of Medicine, 17 West 43d street, New York. Subject: "Inflammation." All physicians and other interested persons are cordially invited.

The New Jersey State Pediatric Society was organized in Newark on February 3, with thirty-four charter members. The following officers were elected: *President,* Dr. Henry L. Coit of Newark; *Vice-President,* Dr. Alexander McAllister of Camden; *Treasurer,* Dr. B. Van D. Hedges of Plainfield; *Secretary,* Dr. Martin J. Synnott of Montclair; *Councillors,* Dr. J. Findley Bell of Englewood, Dr. T. N. Gray of East Orange, Dr. B. P. Craig of Jersey City, Dr. Emery Marvel of Atlantic City, and Dr. F. H. Glazebrook of Morristown. The new society is the outcome of an idea formulated several years ago by Dr. Coit, and now successfully inaugurated through the efforts of several of his enthusiastic co-workers. The objects of the society as outlined in the constitution are: (1) To unite the physicians of the State, who are qualified, for the scientific study of the diseaseses of infancy and childhood. (2) To promote by its concerted efforts scientific medical research in the department of pediatrics. (3) To foster a greater interest in pediatrics among general practitioners. (4) To study the problems of infant mortality and to popularize a knowledge of infant hygiene and of the means for the protection of child life. The annual meeting will be held in Atlantic City on the day preceding the convention of the Medical Society of New Jersey, when only members will attend, to hear and discuss instructive and scientific papers and to transact the routine business of the society. But in order that the society may fulfill its obligation to the profession and indirectly to the public in the interest of the child a series of meetings will be organized in four different parts of the State throughout the year, when papers, designed to instruct the general practitioner in the principles and practice of scientific medicine among children, will be read and discussed. These papers will be presented by well-known authorities on pediatric teaching from the large cities of the United States.

The Rochester Academy of Medicine has elected the following officers for 1910: *President,* Dr. Richard M. Moore; *Vice-Presidents,* Dr. Edward A. French, Dr. Willis E. Bowen, Dr. W. D. Ward, Dr. Albert C. Snell; *Secretary,* Dr. William M. Brown, 666 East avenue; *Treasurer,* Dr. Wesley T. Mulligan.

The New York State Homeopathic Medical Society, meeting in Albany on February 9, 1910, elected the following officers: *President,* Dr. William H. Hodge of Niagara Falls; *Vice-Presidents,* Dr. H. G. Keith of Yonkers, Dr. A. R. Grant of Utica, Dr. Jennie V. H. Baker of Brooklyn; *Secretary,* Dr. Bert S. Clark of New York; *Treasurer,* Dr. Reeve B. Howland of Elmira; *Necrologist,* Dr. John L. Moffat of Brooklyn; *Counsel,* Edwin Van Wormer, Esq., of Albany; *Censors,* Drs. O. S. Ritch of Brooklyn, W. J. McKown of Albany, A. H. Rogers of Corning, and H. J. Ball of Cortland.

The Anderson County (Tex.) Medical Society meeting at Palestine, January 28, 1910, elected the following officers: *President,* Dr. William H. Gohlman; *Secretary,* Dr. E. L. Converse.

Obituary Notes.—Dr. FOLLEN CABOT of New York City died at the Mount Sinai Hospital on

February 13, 1910, at the age of 40 years. Dr. Cabot was a graduate of the Harvard Medical School in 1894. He was visiting genitourinary surgeon to the City and Post Graduate hospitals, consulting surgeon to the White Plains Hospital, and assistant surgeon to the Seventh Regiment, N. G. S. N. Y. Dr. Cabot was a member of the American Urological Association, the New York Academy of Medicine, the Medical Society of the County of New York, the Medical Society of the State of New York, and various special societies.

Dr. William T. English of Pittsburg, Pa., died in the Passavant Hospital on February 8, 1910, aged 61 years. He was a graduate of the Jefferson Medical College in 1871. He was a member of the Allegany County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association. He was a member of the Faculty of the Medical Department of the University of Pittsburg.

Dr. George E. Brickett of Augusta, Maine, died January 28, 1910, aged 85 years. He was a graduate of Dartmouth Medical School in 1846. Dr. Brickett was a surgeon during the Civil War and late attending surgeon to the Kennebec Arsenal. He also served one term in the State Legislature in 1868. He was president of the Kennebec County Medical Society in 1870 and of the Maine Medical Association in 1883.

Dr. William E. Mattingly of Lebanon, Ky., died suddenly at his home on February 1, 1910, aged 66 years. He was a graduate of the Medical Department of the University of Louisville in 1869. He was a member of the Marion County Medical Society, the Kentucky State Medical Association, and the American Medical Association.

Dr. E. J. Morgan of Bainbridge, Ga., died at his home recently. He was a graduate of the Jefferson Medical College in 1865.

Dr. George Griswold Hayward of Boston, Mass., and North East Harbor, Maine, died in Boston recently. He was a graduate of the Harvard Medical School in 1881, after which he was on the staff of the Massachusetts General Hospital. He was a member of the Suffolk County Medical Society and the Massachusetts Medical Society.

Dr. Dennis F. Keefe of Providence, R. I., died at his home on February 1, 1910, aged 43 years. He was a graduate of the New York University Medical College.

Correspondence.

THE UNINSTRUCTED VICTIMS OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—One would think it unnecessary at the present day to call the attention of medical men to some of the most elementary principles in the treatment of tuberculosis, yet the every-day experiences of physicians in health resorts tend to show that it is in these very elementary principles that a large number of practitioners are either reprehensibly careless or inexcusably ignorant.

In the first place, I want to make the assertion, by way of prefacing what comes after, that climate alone never yet did and never will cure tuberculosis. We cannot cure consumption. We can, however, assist Nature in her effort to do this, and the physician at this time seeks to put his patient in the best possible condition to resist and finally overcome the disease which is sapping his vitality. To do this he has two main indications in view: First, to conserve his patient's vitality, and second, to build up his powers of resistance. To accomplish the first he insists upon rest, while the second indication he attempts to meet by forced feeding and abundant fresh air. These rules, I believe, are almost universally accepted among the most casual students of consumption; and yet, in spite of this, we see daily upon the streets of a resort town, tuberculous patients rushing around like a lot of Marathon racers, utterly ignorant that they are doing anything wrong. Recently I had two illustrative cases.

The first patient, running a temperature of from 100° to 103° F., had been conscientiously dragged around town day after day for six weeks by his devoted wife, under the impression that she was doing the very best thing in the world for her husband; and it was only when utter exhaustion rendered these walks entirely unendurable that he consulted me. Examination at that time showed extensive involvement of both lungs, and a temperature of 102° F. Questioning revealed that he was the patient of a New York physician of good standing, who had told him to come down here and keep out of doors, and the climate would do the rest. The second case was similar, though more hopeful. This patient also hailed from New York, and likewise was the patient of a New York doctor. He had received some vague orders about keeping in the fresh air and drinking milk, and as the readiest way of accomplishing this was taking daily walks of from four to five miles. Examination revealed a small cavity in the right apex. Both of these patients had been told that the care of a local physician was superfluous. These are not isolated cases, on the contrary they represent a class. The patients rush around the country in hordes, with the most vague and misleading ideas of their condition and the proper mode of living. They have been told that fresh air is good, consequently they walk their legs off in trying to find it. This walk lasts from a half hour to two hours according to the strength and energy of the patient, after which, conscious of an unpleasant duty well done, he will sit by a stove in a hot close room all day, and at night, still pursuing the fresh air theory, he will daringly lower the window farthest from his bed a fraction of an inch.

For the local physician he has supreme contempt, for his home doctor has warned him against the probability of this rural practitioner loading him down with cod-liver oil and cough syrups; consequently, when, as a last resort he calls one in, he regards with suspicion his directions, and carries them out in a half-hearted way, if at all. If, however, his own doctor had impressed these same directions upon him and advised him to consult a local physician from time to time, it would have materially strengthened the confidence of the patient and greatly facilitated the local doctor's treatment.

Please remember that in prescribing fresh air, eggs, milk, or what not, you are doing this in lieu of the use of drugs, and just as you would not for a moment think of telling a patient to take "some strychnine," "some morphine," or "some digitalis," for pity's sake cut loose from generalities and be specific, when you are sending any of these poor sufferers away from home among strangers, and tell them just how many eggs, how much milk, how much air, and how little exercise they need. If you have not time to do this verbally, keep printed slips with full directions, and hand these out to your consumptive patients when you send them away. Otherwise you are doing a great injustice to yourself, your patient, and the resort doctor into whose hands they ultimately fall, at a time when, perhaps, his treatment will be of little avail.

F. Julian Carroll, M.D.

Summerville, S. C.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL MEMBERS OF PARLIAMENT—OFFICERS OF HEALTH ON THE POOR LAWS COMMISSION—THYROID AND ANTITHYROID PREPARATIONS—PANCREATIC REACTION—BACTERIA AND DIGESTION—X-RAY VICTIM—SURGICAL CONVALESCENT HOME—LIBEL BY MEDICAL ASSOCIATION—TROPICAL MEDICINE—OBITUARY.

London, January 28, 1910.

The general election is not yet over and has preoccupied everyone all the week. Among the doctors who have obtained a seat in the new Parliament are Sir W. Collins, Sir W. Foster, Sir G. H. Pollard, Sir R. J. Price, Sir G. S. Robertson, and Drs. Addison, Dixon, Hillier, Chapple, Rainy, Dillon, Lynch, and O'Neill.

You will see we shall secure the average strength of the profession in the House. Five of the above are new to Parliamentary life. The others had seats in the last House and have been reelected.

Since the issue of a majority and a minority report by the Royal Commission on the Poor Laws we have had a fairly continuous series of debates on the subject from which it may be hoped great benefits will eventually accrue. There are people who are enthusiastically for the conclusions of one or other report, others who try to reconcile their differences, and others again who endeavor to master the whole subject. Among those practically as well as theoretically interested the Medical Officers of Health are naturally affected, and their society has already given two or three meetings to the consideration of the problems involved. At one of them Dr. Greenwood laid before the society the view which he thought was generally entertained by the Poor Law doctors themselves. At another the minority report was more carefully examined, especially concerning the proposal to put an end to the overlapping which unfortunately exists between the Poor Law and the Public Health services. The unification of these two services would provide an independent organization which some thought should be under a new public health department and others would leave to the supervision of a reformed Poor Law authority. The minority report would commit the unified service to the health committees of the county and borough councils, with salaried medical officers devoting their whole time to the work, and would include clinicians as well as sanitarians, and such other officers as might be required to provide efficient domiciliary inspection, advice, and treatment, all under a central public health department in London. Doubts were expressed as to whether the Medical Officers of Health could really do more than they had done, and especially if they would be able even to supervise clinical work. If school clinics were to be promoted, could the men doing the work in them be subordinate to the Health Officer? Other doubts suggested concerned rather the capacity of County Councils to take over more work and the formation of a committee analagous to that on education was proposed as more suitable. On the other hand it was maintained that the Poor Law service had not been treated in a reasonable way but crippled in every possible manner by the central authority and this was the only reason that the Public Health service had advanced more rapidly and gained more consideration. It was remarked, too, that many cases of illness were not thought much of by the patients, though as regards the State they were of great import. Such persons neglected medical aid, which they objected to pay for, and that was a reason why treatment must be compulsory if it were to be of any use from the public point of view. If this be admitted, the conclusion would be that to prevent the spread of such diseases inspection and early treatment are desirable so far as the public is concerned.

The effects of thyroid and antithyroid preparations on rats were the subject of a communication to the Royal Society of Medicine (Pathological Section) by Mr. W. Edmunds, who related ten experiments. Four controls remained healthy. One thyroid preparation produced severe illness or death within twenty days in two of the rats; another preparation in eighteen or nineteen days. An antithyroid preparation had no effect in thirty-nine days. A mixture of thyroid and antithyroid was as fatal as thyroid. Post mortem: The suprarenals were enlarged and dark in color, as compared with the controls. The microscope showed that they were engorged with blood and contained hemorrhages. There was no change in the thyroids or other organs. The conclusion suggested was that thyroid feeding in full doses (10 grains three times a day had been given with the food in the experiments) causes congestion and hemorrhage into the suprarenals, which is not prevented by equal doses of antithyroid.

In the same section on the 18th inst. some experiments were described by Drs. P. J. Cammidge and H. C. G. Semon as to the pancreatic reaction. They reported that chronic pancreatitis caused by an ascending infection from the duodenum gave rise to the characteristic reaction in the urine, but on extirpation of the pancreas after three weeks the reaction disappeared. Yet simple extirpation did not produce the urinary reaction. This seemed to indicate that the disturbed metabolism, caused by interference with the functions of the gland, was not the cause of the reaction. They suggested that some substance set free in the tissues of the gland gave rise to the pancreatic crystals which had the characteristics of a pentosazone.

Sir E. Ray Lankester, in his presidential address at the Royal Microscopical Society, referred to the relation of bacteria to digestion, as to which he said science was only at the starting point of an obscure problem which he recommended for investigation as likely to yield valuable results. The lactic ferment checked the life and activity of putrefactive bacteria which produced poisons that were absorbed. So the use of lactic acid seemed important, but the problem presented was what business these parasites had in the alimentary canal at all. There were fifty or sixty species of them and it was remarkable that they were tolerated. So some had suggested they were beneficial and experiments were made to determine whether vertbrates could do without them. Chickens totally deprived of them had drooped and died. When a fresh supply was given to those drooping they picked up again. On the other hand, some grubs of blowflies did very well on sterilized meat, but the majority preferred it in a state of putrefaction. It seemed too difficult to insure sterilization for young mammals, but the general result of investigation in the case of bats indicated the possibility for highly developed adults to carry on their digestion without bacterial assistance.

Sir William Treloar has opened a subscription on behalf of a "victim to science," *i.e.* to *x*-rays, in the person of Mr. Cox, a coworker with Dr. Hall-Edwards, who lost both hands but has recovered to a great extent and can practice his profession partially. Mr. Cox, however, is a more lamentable case. He has lost his right arm, his left hand middle finger, the whole hand being withered. Still worse, he has contracted rodent ulcer and a cancerous condition of his face, chin, and jaw. A truly pathetic result, this, of his devotion to *x*-ray investigation in the early period. It is said that the improvements he effected have gone far to render *x*-ray workers safer from such terrible consequences. It is also said that he worked day and night during the South African war to secure the military surgeons the most perfect apparatus. Six years of suffering, which repeated operations have done little to relieve, have reduced him to a condition in which no hope remains to encourage him.

The Home of Recovery for Surgical Convalescents projected by Miss Fraser-Tytler and Mrs. G. F. Watts, for which over £30,000 had been raised, is rendered possible by the munificent gift of £100,000 from Mr Ernest F. Schiff in memory of his brother, and presented through Mr. Mayo Robson. The Schiff Home is for surgical patients discharged from the general hospitals who are not well enough to discharge their ordinary duties, but not requiring such active surgical treatment as to occupy beds needed for more urgent cases.

A jury awarded on Monday £750 damages against the British Medical Association for libel on Major G. T. Rawnsley of the R. A. M. C., contained in comments made in the *Journal* on a lawsuit of the Major's. A note was subsequently inserted to the effect that they did not desire to cast any reflections on the Major, but he did not consider that a sufficient apology and brought an action, with the result stated.

Sir John Craggs gives a prize of £50 annually to the student, past or present, of the London Tropical School of Medicine, who has made the most valuable contribution to the subject during the year. This year the prize is awarded to Dr. J. A. Turner, of Johannesburg, for "an account of some Helminthes occurring among the South African natives."

The chairmanship of the Liverpool Tropical School has been accepted by Mr. W. H. Lever in succession to the late Sir Alfred Jones.

The death occurred of Mr. W. W. Wagstaffe, late of St. Thomas's Hospital, at the age of 67. He took B.A. Lond. in 1861 and M.B. 1867. He was elected on the surgical staff of the hospital and became also lecturer on anatomy. He retired from practice some years ago. He was joint editor of Le Gros Clark's "Outlines," Helberg's "Atlas," and editor of Mayne's "Medical Vocabulary." His own "Human Osteology" appeared in 1875. He contributed freely to the *Journal of Anatomy and Physiology* and also to St. Thomas's Hospital Reports for several years.

Dr. Stanley B. Atkinson, J. P., died on the 18th at the early age of 36. His career had been most brilliant He graduated in arts and law at Cambridge, in medicine at London. He was also a barrister-at-law, was secretary of the Medico-Legal Society, and held other of-

fices. He wrote "Golden Rules of Medical Evidence," the "Office of Midwife," and the "Law of General Practice," and contributed to both medical and legal societies and journals. He took a very active part in the election, which was probably too much strain for a weak heart.

Department Surgeon-General Robert Rouse, I.M.S., retired, died on the 20th inst., aged 77.

Dr. Page-May, M.D., D.Sc. Lond., F.R.C.P., etc., died suddenly on the 19th, aged 46. He had given up practice to devote himself to the chair of neurology and researches therein at University College (an unpaid post). Four years ago he described the fibers now named May's tract. He had spent several winters in Egypt, returning to London each summer.

Dr. Septimus J. Lee, who died on the 10th inst., was resident medical officer to the Epilepsy Hospital, Maida Vale. He only qualified last year at the two London colleges and has thus soon died of acute tuberculosis.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 3, 1910.

A Case of Wonderful Vitality.—L. M. Palmer reports the case of a powerful man who lived thirty minutes after being knocked by a locomotive, two wheels of which passed over his body. The intestines were scattered over the track and surrounding dirt. There was only a little blood to be seen. He was given a grain of morphine, it being expected that each moment would be his last. The man complained only of his legs, said there was something on them that was hurting him and begged to have it removed. He was placed beside the track and in a few minutes died. Careful examination of the body after death showed the liver, kidneys and intestines one mangled mass of tissues. The spinal column was entirely crushed: also the aorta and its branches. The right hip was crushed and the right testis torn from its scrotum. The chest was not injured nor opened, nor was the head bruised. Up to within five minutes of his death he had a fair pulse and a normal respiration, and not as much shock as the reporter has frequently seen after a far less severe injury.

Unsuspected Diabetes, a Cause of Rapidly Fatal Coma.—W. W. Miner reports the case of a stout woman, a domestic who, while washing, suddenly complained of not feeling well, went upstairs, and became unconscious. In three and a half hours she died in coma. There was no paralysis or stertorous breathing, the pulse was not rapid, the respiration was comparatively free, there was no twitching, spasmodic movement, nor convulsive attacks. Edema was absent. She had been supposed to be in perfect health before the fatal attack. There had been no urinary symptoms and no edema. Bowels were regular and there had been no nausea, though she had had considerable gas in her stomach. She was not subject to fainting attacks, had had no pain around her heart, headaches nor disturbed vision, though her sight was not very clear. Soon after her death the author obtained by catheter a few ounces of urine. This was of ordinary color and fairly clear. Subjected to the usual Fehling test it gave a heavy precipitate of the yellow sub-oxide of copper, but was apparently without a precipitate of albumin. The reporter, therefore, came to the conclusion that her death was probably due to diabetic coma and gave a certificate to that effect. The paper closes with a series of extracts from modern textbooks on diabetes in general and coma from it in particular.

Clinical Significance of Curds in Infant Feces.—This subject is considered by F. B. Talbot, who says that large, tough curds are usualy solid. When placed in cold water and shaken up they quickly sink to the bottom of the vessel and can thus be easily separated from the surrounding mass. They are composed of casein, which on coagulating entangles the milk fat in its meshes. If the milk contains 4 per cent. of fat, the curds will contain it in large amount, while if the milk is skimmed the amount of fat will be very small. These curds pass through the intestine practically unchanged and are digested only on their surface. Most of the fat is unchanged neutral fat, while a very small amount is split up into fatty acids and soap. These curds always contain a high percentage of nitrogen. Small, soft curds appear as white flakes or pin-head elevations. Both forms may appear in the same stool. If shaken out in cold water they appear suspended in it. Most of them are in the form of fatty acids and soap and contain very little protein. If there is doubt whether the curds are fat or casein, they may be placed in 10 per cent. formalin and allowed to stand from four to six hours. The casein will by this time be very hard and the fat curd soft. The fact that there are two kinds of curds makes their differentiation of importance. One kind indicates that the fat is not entirely utilized, and the other that the casein is not completely digested. This difference accounts for many of the difficulties of infant feeding and solves many of the perplexities in prescribing food for dyspeptic babies. If a baby shows signs of indigestion, does not gain in weight, and is passing stools which contain tough curds, casein is at fault and should be replaced by some other food, and if another baby shows signs of indigestion, stops gaining weight, and passes many soft curds in the stool, fat is at fault and its amount in the food should be diminished. Whenever either of these foods is diminished, one or both of the others should be increased so that the caloric needs of the child will be supplied. Symptoms of indigestion disappear when this is done and the infant begins to gain in weight. These general principles do not, however, apply to all babies because sometimes an excess of one food complement will so change the digestion that another complement will also appear in the stools. Tough curds may also appear in the stools of infants who are gaining and happy and show no other signs of indigestion. In such instances it is not necessary to diminish the amount of casein in the food. The indication is not to increase the amount of casein beyond the physiological limit. Tough curds are never seen in the stools of breast-fed infants.

New York Medical Journal, February 5, 1910.

Further Contribution to the Study of Vasomotor and Trophic Disturbances in Hysteria.—A. Gordon refers to the recent views of Babinski, who recently advanced the opinion that the anesthesias and analgesias observed in hysteria are exclusively the result of suggestion induced by the physician during examination. The author believes that Babinski is wrong, and to support his own position relates the history of a young woman who underwent a severe nervous shock, succeeded by others, and who developed the usual sensory symptoms. Their onset, evolution, and character were all typical. Unusual vasomotor symptoms were present. The erythema which developed caused the patient's earnest request for relief therefrom, as it interfered with the work. The sudden onset of redness and itching of the nose after mental shocks and the other factors in the case go to show that the vasomotor and other disturbances of this case were genuine and not evoked in any way by the examining physician. When, according to Babinski, the patient is told that her skin is touched, and not asked any questions, the results will be different from those of the same procedure in which questions are asked. The latter method is advised by Babinski as the correct one. The author, however, has always tried this method in this test and yet believes in the genuineness of hysterical anesthesias and analgesias. The foreign author also denies the existence of trophic and vasomotor disorders of hysterical nature, and all published observations he regards as misrepresented by the judgment of the examiner or as simulated by the patient. Injuries, erosions, or other disturbances of skin or mucous membranes are the result of self-mutilation, so to speak, as hysterical individuals are prone to deceive or commit other abnormal acts.

The Ounce of Prevention.—S. W. Newmayer refers to the study of late years in regard to the health of children, and also to the recent efforts put forth in a municipal sense to rouse adults to the necessity of taking heed to sanitary methods. He calls attention to the imperfections of the present school books, which teach of physiology and sanitary matters in general. Too much space is given to the effect of narcotics. In some States one-quarter of the book must be given up by law to these topics. Too much space is also given to the purely anatomical division of the subject. Almost as much is included in some textbooks for children as is included in the curriculum of the first year medical student. Such books fail in the ordinary school room. Hygiene can be made effective and interesting with little reference to other branches. Anatomy cannot be made palatable. The entrance requirements for admission to a first-class medical school require neither knowledge nor previous study of anatomy or physiology. These branches are not on the lists of branches required for entrance examinations, but physiology and hygiene are among the elective branches, and together on examination total one point out of a total of thirty points required for admission. The first year of a four or five years' medical course requires the studying of the bones and muscles and the peripheral nerves and vessels; in physiology, general biology, and possibly digestion and circulation. Hygiene

is practically completed the first year. The comparison may seem ridiculous, nevertheless compare these subjects with the requirements of the elementary schools—children between the ages of six and fourteen years. The author does not mean to infer that we are overtaxing their delicate brains, for it never enters, and the little that does is memorized and leaves as fast as it is acquired. The available time for these studies is little, so it should be consumed entirely in purely practical problems of hygiene. Out of a total available 1,500 minutes school time each week, there is alloted 75 minutes to physiology, which includes anatomy and hygiene. In the first four grades there is taken part of the 200 minutes alloted to language.

Enuresis.—This is a general paper by F. L. Wachenheim. After a full enumeration of predisposing and exciting causes, he takes up the question of treatment. As a rule the onset of puberty witnesses a relief of many cases. No drugs have seemed to be of any permanent benefit except belladonna, hyoscyamus, and allied mydriatics. The author condemns perineal vesication, cantharides, cautery to the neck of the bladder, etc. If the latter ever does any good it must be by suggestion. Opinion differs among authorities as to the value of faradization and massage. The danger of starting masturbation in this way must not be forgotten. Epidural injections of normal salt solutions is a dangerous remedy for such a harmless disease. Certain psychotherapeutic measures have resulted in success. In one the child is compelled to urinate at regular hours day and night. The usual methods of cutting off all fluids during the late afternoon and evening are suggested. This, however, is merely palliative and auxiliary. Teachers should be informed of this peculiarity on the part of their charges, who should be dismissed at regular intervals. Raising the foot of the bed is probably useless, for the tissues at the neck of the bladder are not the ones at fault. The affection is best regarded as a nervous tic, and treated by the general measures usually applicable to this class of affections. Suspension of the incontinence of even twenty-four hours is an encouraging sign; it may mark a complete cessation or be followed by recurrence; the latter may come on after a cessation of many days. It is therefore wise to continue the training for a considerable time, at least two months, after the incontinence has ceased; the nocturnal rousings may be omitted after about a month, but the strict observance of the diurnal intervals should be continued at least a month longer. After all is said, the main essentials in the treatment of enuresis are patience and persistence on the part of all persons interested; very few cases will be found to hold out against this combination.

Journal of the American Medical Association, Feb. 5, 1910.

Infantile Bacillary Dysentery.—W. P. Lucas, J. G. Fitzgerald, and E. H. Schorer have studied the serodiagnosis of infantile infectious dysentery. The first two testing the agglutination and fixation reactions in both the Flexner and Shiga varieties of the disease, and the last named giving attention to the forms of bacilli obtained in relation to the clinical aspects of the individual cases. The value of the agglutination reaction, which has been generally employed by investigators, would seem by common consent to be not very great on account of its delayed appearance and relative infrequency. The authors think, however, that the methods have not been so uniform as desirable and the susceptibility of the organism employed as a reagent and its relation to the bacillary type causing the infection should be considered. The reaction of fixation has been employed with success in diagnosis of adult dysentery by Dopter. His observations that both mannit-fermenting and mannit-non-fermenting strains gave this reaction have led some to consider it less specific than the other, but Haendel has shown that this idea is erroneous and that in properly chosen minimal doses only the individual strain causing the infection or immunity would cause fixation. The conglutination reaction has been hitherto of interest in the more theoretical studies of immunity. In 1906 Bordet and Gay described a thermostabile (56 C.) "colloidal" substance in bovine serum which has the property of producing a characteristic clumping and increased dissolution of red blood cells that have been treated with both a sensitizer (heated hemolytic serum) and an alexin. A probably analogous substance was described about the same time by Manwaring. Streng has suggested the possible employment of this reaction for the diagnosis of infections of bacterial origin. The authors describe their method of experimenting both with serum diagnosis and with bacteriologic study in detail and tabulate their result. An analysis of these tables is given. There were 45 cases studied, in 38 of which the bacillus of dysentery was found either of the Flexner or the Shiga type. Comparing the results with the two types they find: "As regards the Flexner strain of bacilli: 1. Agglutination occurs rarely in negative cases (6.6 per cent.), and frequently in cases of dysentery (53.5 per cent.). Fixation occurs not infrequently in negative cases (28.5 per cent.), but more frequently in positive cases. Conglutination does not occur in the negative cases, but occurs in 63.1 per cent. of the positive cases. 2. As regards the Shiga strain of bacilli: Positive reactions do not occur in negative cases. In the positive cases agglutinations were present in 24.4 per cent., fixations in 45.2 per cent., and conglutinations in 21.6 per cent." It is evident that the conglutination reaction is superior to the other two tests in the diagnosis of dysentery infection and as the relatively better indicator of the bacillary type. It is not to be confused with agglutination. This is evident by the appearance of the tube (clear with flecks on the sides) and other facts shown in the tables. Reactions with the Flexner strain are much more frequent than with the Shiga strain, partly, the authors think, because of a greater agglutinability. No positive conglutination reaction was obtained in control cases. Conglutination was obtained in 50 per cent. of the cases with the Flexner organism.

Corn and Pellagra.—D. R. Silver says that, respecting pellagra, two statements can be made rather confidently: 1. Where corn is not eaten, pellagra does not exist. 2. The eating of good corn or cornmeal will not produce pellagra. The latter proposition, he says, is self-evident; otherwise the whole West would suffer from the disease, whereas it is more prevalent in the Southern and Atlantic border States. The only wonder is that it did not appear or be recognized sooner. It is evident that the poorer people of the South and Atlantic border States furnish the greater number of victims. Well-to-do people may get damaged cornmeal when it is kept in stock, but to a very much less extent. It is sent to the South and South Atlantic border of our country with the purpose of finding a market which it cannot obtain in the North or in regions where it is generally grown. He reproduces a letter from Mr. Thomas C. Marshall, ex-president of the Ohio Grain Dealers' Association, which contains some interesting statements. It says that much grain reaches the market heated and is sent to driers and much of it gets to the mills, though in bad condition. These driers are situated at the terminal stations—Philadelphia, Baltimore, Buffalo, Cleveland, and Columbus, Ohio—and the South and East is an excellent market for their products. Much of it is also exported. The millers make their profit by mixing it with good corn and will probably continue to do so until restrained by law. Those to whom cost is of more importance than quality are the consumers, and they pay the penalty. Silver says whether the inferences in this letter are correct or not, the facts can easily be made known by the Public Health and Marine Hospital Service, and if the charges are sustained steps should be taken immediately to stop the traffic in spoiled corn. He says also that it is worthy of thought whether the policy of purchasing supplies for public institutions by the method of competitive bidding is not fraught with great danger. Purchasing in the open market as need requires would be much safer. It is possible that to the policy of competitive bidding may be traced the prevalence of pellagra in some asylums and schools. At a Baptist orphanage at Nashville, Tenn., there were seventeen cases, and the physician in charge says that there was every evidence that the disease was contracted in the institution.

Primary Sarcoma of the Spleen.—Camillus Bush reports a case in a man of 48. Splenectomy was performed, but the patient died with metastases six months after the operation. The growth appeared to be possibly due to an injury received some three years before the appearance of the symptoms. The growth was rapid and painful, and led to a rupture of the spleen. The removal of the spleen was followed by anemia of rather a severe type, but no lymphocytosis. There was also enlargement of the liver, reaching its maximum five weeks after operation and gradually subsiding under treatment with *x*-ray and Coley's fluid. There were finally recurrence of the growth and metastases causing death. A special feature was the occurrence of extreme cyanosis after rupture of the spleen. The significance of this is not explained.

Laryngeal Diphtheria.—C. H. Shutt thinks that non-instrumental methods are worthy of more frequent trial, at least in hospital practice, in cases of laryngeal diphtheria with only slowly increasing dyspnea, only moderate exhaustion, and slight cyanosis. The local measures consist chiefly in inhalations, securing of favorable surroundings and perhaps the induction of vomiting to aid in removing loosened membranes. General medical treatment consisting of antitoxin and stimulation as needed, cathartics,

diuretics, etc., should be employed as in pharyngeal diphtheria. Antitoxin should be employed in all cases and as early as possible, and he prefers moderate sized doses repeated every four to six hours as more effective and less depressing than massive ones. When the patient is very weak, toxic, or much cyanosed, surgical or mechanical measures are indicated and the choice is between intubation and tracheotomy. The author's conclusions are that physicians should be prepared to treat laryngeal diphtheria, which usually presents, as an emergency. The physician may find himself without intubation instruments in an emergency and be compelled to attempt tracheotomy. Non-instrumental methods of relief are worthy of more frequent trial, especially in institutional work and in those cases in which dyspnea is increasing slowly, exhaustion is moderate, cyanosis is not severe, and the surroundings are favorable. Intubation may be performed in cases in which the symptoms indicate recent and closely adherent membranes. It should be employed only when intelligent nursing may be had and when the physician is within easy reach. Every physician should be familiar with the technic of tracheotomy.

The Lancet, January 29, 1910.

Acute Dermatitis Due to Bichromate of Potassium.—Two cases are reported by R. P. White. Case 1 was that of a dyer of 57 years who after four or five weeks at his employment began to have a roughness of the arms and swelling of the hands, the backs of which were itchy, but not servecly so, and he had no pain. The oftener he worked in the dye house the more severe were his symptoms. At the end of the seventh week an inflammatory rash spread all over his face, and he applied for treatment. On the backs of his hands, forearms, and arms as high as the rolled-up sleeves, the front of his chest where his shirt was opened under his chin, round the throat and over the whole of the face, and on the ears was a bright red, diffuse, erythematous rash, peeling in places in yellow flakes. The initial lesion appeared to be a scaly papule with a red spreading areola. At the inner side of both elbows the inflammation was intense, and moisture was freely exuding from beneath the thin, scaly crusts. Case 2 was a fellow workman of 30 years, whose rash did not appear for three months. He never used gloves and lifted the material out of the dye vat with bare hands. In general, his condition was like that of the other man, but his palms were very moist, while those of the other man were horny, thick, and dry, and around their periphery were deep cracks and fissures. The cessation of the use of chrome used in their work and simple soothing treatment led to perfect recovery in a few weeks. The author gives a description of the mens' work. One and a half pounds of bichromate of potash are dissolved in 200 gallons of water, and the goods are boiled in this solution one hour. It was from work with this solution that the dermatitis was contracted. In both these cases the subjective symptoms complained of were very slight; chrome sores are well known to be painless. These men had only symptoms of slight irritation. As a rule, this salt in solution is said not to attack unbroken skin, but if associated with heat and moisture the preparation is much more active. Many exposed to it in this form are especially liable to irritation of the nasal septum, which fact is said to be due to a deficiency in blood supply. Certain rules are laid down which should be enforced in the conduct of workmen employed in institutions in which chromium salts are used. The employment of some form of grease on the skin is said to be helpful in preventing this form of dermatitis. Any instrument used to lift material out of such solutions should have a flange to prevent its running down on the hands. Each workman who comes in contact with the dust of chromium or with its solutions ought to wash all exposed parts freely, and among others, the orifices of the nose with a reducing agent such as weak bisulphide of soda.

An Infant as a Carrier of Enteric Fever Infection.—A. Oberdorfer reports such a case occurring in a breast-fed child of eleven months, who contracted the disease from her mother who died. About seventeen days later the child was taken ill of the fever. In three weeks a man who had slept with it came down; as still later did a woman who had washed for it. The only symptoms in the child were wasting diarrhea and a positive Widal reaction made some six weeks after the inception of the disease. Although it might be suggested that the cases in the district in contact with the baby were due to the original cause of the epidemic, yet the sequence of the cases and the result of investigation eliminated this possibility, and it was decided that the baby acted as a carrier and that infection from it was the cause of each case in the series referred to.

Retention Pneumonia.—Notes on a case are reported by F. I. Hathaway, whose patient was a stout girl of 22 years. The history is interesting for the following reason: 1. The patient had suffered from and was confined to bed with a most irritating cough, no physical signs for which could be found. The abdominal pain of the distressing cough induced her to refrain from the act of coughing as much as she could, and in this way, the author thinks, the retention of the pneumonia was brought on by the accumulation of secretion. 2. Except for the first and second days, the temperature did not rise above 99°, while all through the illness the patient's general condition was excellent. The respiration-pulse ratio was increased and the signs of lobar pneumonia were particularly well marked and did not begin to clear up till the tenth day of the disease. 3. The report on the sputum was "almost a pure culture of the pneumobacillus of Friedlander. There was no crisis. The râle redux appeared on the tenth day, twenty-four hours later the dullness being still present, but over only a small area. On the thirteenth day it had almost cleared up, while the bronchial breathing had gone and the redux crepitations were clearing up. Recovery was complete. A peculiarity of the sputum was that while there was almost a pure culture of F's bacillus, there were no pneumococci. Various authors refer to this peculiarity, and also that one occasionally meets with afebrile pneumonia and that ether pneumonia is often lobular in type.

British Medical Journal, January 29, 1910.

Treatment of Ringworm.—E. L. Jenkins says that the use of the *x*-ray is in the country often unavailable or impracticable. In dealing with pediculosis in his hospital wards he always uses the essential oil of sassafras, which he regards as a specific. When both periculosis and ringworm existed in the same scalp, the latter disease also appeared benefited. This led him to try the remedy for ringworm alone. So far the results have been most effective. The hair is cut closely around in order to identify the patches, and the oil is applied twice a day by means of a camel's hair brush. This treatment is continued a few weeks or so, as the case may indicate. No irritation is produced, and the application is pleasant to use. Not only is the spread of the affection prevented, but the fungus is destroyed with certainty in two or three weeks, this certainty being recognized by the development of fine new hairs.

Some Results Obtained from the Local Application of Solid Carbon Dioxide.—E. R. Morton has used this remedy in lupus, warts, nævi, and moles. His paper is a summary of his results thus obtained. One case of lupus vulgaris, not a very promising one, did not do well. The patch was near a joint, where it was difficult to maintain firm pressure, and the great amount of movement incident to the nearness of the joint was also an unfavorable feature. In a case of lupus erythematosus, results were fairly satisfactory, though no more so than has been found to be the case with other remedies. Of four cases of moles, three were cured and one improved. This was in a small boy, but of the size and hairy growth one would expect on a full sized man. The hair was removed, but is too soon to say if the epilation will be permanent. Of twelve cases of warts, nine were cured, two still under treatment, and one disappeared. The crayon is trimmed to a size corresponding to that of the wart, application made with firm pressure until a narrow ring of frozen, healthy tissue is made around the base of the growth by conduction from the center. One hundred and five cases of nævi presented 129 of the lesions for treatment. Of 85 capillary nævi, 74 were cured by one application lasting 40 seconds, six had two applications, two had three, and two had four. Of 32 cavernous nævi, 20 were cured by one application, four had two, two had three. In all cases in which capillary nævi and cavernous nævi were both present, the capillary part was treated by CO_2, and the rest by electrolysis. The author has now under treatment some cases of the "port wine" mark, and he considers the results as promising, though perhaps no better than those from radium. He finds the CO_2 applications practically painless and of only a few seconds' duration. He notes with regard to his port wine cases that the first application seems to have little or no influence in reducing the depth of color even after waiting three weeks. A second application is marked in its effects, and may be sufficient.

The Therapeutic Value of Carbon Dioxide Snow in the Treatment of Vascular Nævi, Moles, Etc.—A second paper on the same topic is submitted by J. M. H. Macleod. This author secures the snow by means of liquefied gas in a cylinder allowed to play into a baize bag, the inside of which quickly becomes covered. The

snow is then scraped off into the mold it is desired to use. Generally the applicators are shaped like an aural speculum, into which a vulcanite plunger is fitted, so that the application may be made with the amount of pressure desired. The variety of lesions treated is about the same as stated in the paper of Dr. Morton, except that Dr. Macleod has used the remedy for rodent ulcers. He says that it will destroy these, provided they are superficial and do not involve deep structures. Such treatment does not seem, however, to him to give better results than the actual cautery, and if the lesion penetrates deeply it is less efficacious than radium. In regard to nævi and tissues in general, the author says that after the tissue is frozen at the base it thaws in about a minute, and that a few hours afterward an inflammatory reaction sets in. If the lesion treated is larger than the largest applicator it can be attacked piecemeal, or a piece of thin lead is placed between the lesion and the applicator, as the metal conducts the cold, and by it irregularly shaped lesions can be treated exactly. When the lead is interposed a longer exposure is necessary than where the applicator is applied directly to the skin. If blisters form, it is wise to use dressings of some mild antiseptic ointment to prevent contamination with pyogenic microorganisms. As a rule, the pain complained of from the applications of the snow is mild and trivial. Both authors believe that there is a promising future for this form of cautery.

Appendix Dyspepsia.—B. G. A. Moynihan reaches the following conclusions: (1) The symptoms of both gastric and duodenal ulcer, especially the former, may be exhibited with great fidelity in cases in which no structural lesion can be found in any parts. (2) In many cases of gastric ulcer, in which the symptoms, pain, vomiting, and hematemesis, are present, and in many cases of intractable dyspepsia of a capricious kind, the only pathological change discoverable during operation is a chronic inflammation of the appendix. (3) Removal of the inflamed and obstructed appendix is generally followed by instant and complete relief of all former dyspepsia. The cessation of symptoms, however, may come only by degrees and with the lapse of many weeks. (4) No operation for supposed gastric or duodenal ulcer is complete until an examination has been made of the appendix, small intestine, and mesenteric glands, that is, of the midgut. (5) If, in such an operation no lesion can be found in the stomach or duodenum, it is not permissible to perform any operation as gastroenterostomy. This operation has results not surpassed by any other when performed in properly selected cases. It is worse than useless in chronic appendicitis. (6) The mimicry of the symptoms of gastric ulcer in these cases is due to an exaggerated action of the pylorus. This tumult of contractile activity can be recognized when the stomach is inspected. (7) Investigation is necessary to ascertain the frequency with which the mucous erosion of the stomach (the "acute" or "medical" ulcer) is dependent on a primary lesion in the appendix or intestine.

Münchener medizinische Wochenschrift, January 11 *and* 18, 1910.

The Presence of Fatty Acids in the Infant's Intestines.—Hecht has investigated the subject of the presence of various fatty acids in the stools of infants, in connection with the statement that many of the severe gastrointestinal disturbances of infancy are due to the formation of the higher fatty acids. The stools of healthy and ill infants were obtained in quantity, distilled, and tested for the acids by various methods. In a series of breast-fed infants he found that a fairly large amount of the volatile fatty acids might be present in the stools of very young nursing infants in perfectly good health, but that an abnormally large amount might not be well borne. A marked decrease in the fat in the food, however, did not in every case improve the child's condition or reduce the fatty acids found in the stools. In such cases the volatile fatty acids may have been formed from the carbohydrates in the food. Lactic acid was present in less amounts than the volatile acids. On artificial feeding a great increase in fat in the food caused a decrease in fatty acids in the stools, as also did a high carbohydrate, low fat mixture. The decrease of fatty acids with the increase of the fats of the nourishment is explained by the antagonism between fermentation and putrefaction in the intestines; the increased putrefaction due to the fats decreasing the formation of the fatty acids by fermentation. The conclusion drawn from the experiments is that the presence of a certain amount of fatty acid is necessary for the normal course of digestion. It is possible that in acidosis the feeding of organic acids might cause improvement in the condition, in that the latter being burned to carbonate might increase the alkalis of the body.

Phagocytosis and Arneth's Blood Picture.—Busse considers the statement of Arneth that the effectiveness of a leucocyte in phagocytic activity is in proportion to the number of its nuclei. His conclusions are as follows: (1) In the blood of healthy men all classes of neutrophilic leucocytes—according to the classification of Arneth—have similar phagocytic activities, at least in test tube experiments. (2) Neutrophilic white corpuscles from inflammatory and postoperative leucocytoses occur in the same ratios. (3) Leucocytes from healthy men and from inflammatory and postoperative leucocytoses have the same phagocytic activities. (4) Arneth's law that leucocytes with few nuclei have less value in protecting the body than those with more nuclei, is of no value in test tube phagocytosis.

Prolapse of the Genitalia in Late Primiparæ.—Fetzer says that the late occurrence of the first labor is the most important cause of genital prolapse. A woman who has her first child before the age of twenty years very rarely has any lasting organic trouble from the birth trauma. Such an early age for labor seems to protect the patient against the disease. The early date of the first birth gives the ability to have more children without injury. The later the first labor occurs so much greater is the probability of acquiring a prolapse following it. This probability increases very slowly and regularly until the twenty-seventh year. From then on each year in age that the first gestation is postponed increases the chance of genital prolapse very rapidly, so that in later primiparæ the probability of the affection is many times greater than it is in early primiparæ. The number of pregnancies has no etiological significance.

The Transformation of Tubercle Bacilli of the Human Type into the Bovine Type.—Eber has been carrying on a series of investigations into the two types of tubercle bacilli in the Veterinary Institute of the University of Leipsig. The results of these investigations showed that it is possible by certain methods by injection into cattle so to change tubercle bacilli obtained from tuberculous material from men, which had all the characteristics of the typus humanus, that on further injection into cattle they became highly virulent for the latter, and in both culture and rabbit experiments they resemble the bovine type of the tubercle bacillus. The most successful form of inoculation for these experiments in transmutation of type was the injection in the peritoneal cavity. In his experiments the author succeeded in transforming three of the seven strains of human bacilli obtained at autopsy from the lungs of men into the bovine type. The author considers the results of his researches to be a further advance in our knowledge of the relation of the human and bovine forms of tuberculosis.

Tubercle Bacilli in the Stools in the Diagnosis of Intestinal Tuberculosis.—Klose says that the exact diagnosis of intestinal tuberculosis is no easy matter. He has made an investigation to prove the exact value of finding the tubercle bacilli in the stools as a diagnostic sign of intestinal disease. He made simple smears of stools stained by the Ziehl stain, and when this failed the new antiform method was used. His patients were sixty definite cases of pulmonary tuberculosis. Six of these showed some clinical signs of intestinal tuberculosis. In these six the bacilli were possibly slightly more numerous than in the rest of the cases. Nevertheless a simple smear showed the tubercle bacilli in 47 of the 60 cases, and examination by the antiform method in eight more, leaving but five negative cases. As in but six of these was there any reason for suspecting tuberculosis of the intestines, and as all sixty had tubercle bacilli in the sputum, the author concludes that in the great majority of those cases in which the organisms were found in the stools, they were there simply as a result of swallowing of sputum, and that such a finding is in no way diagnostic of tuberculous disease of the bowels.

Deutsche medizinische Wochenschrift, January 13 *and* 20, 1910.

Chronic Circumscribed Serous Meningitis of the Brain.—Oppenheim and Borchardt discuss this subject. Oppenheim reports a case of a girl of seven years who showed symptoms of a cerebral tumor. Over a period of eighteen months the child was given antisyphilitic treatment, which caused marked remissions in the disease. Finally, no further improvement occurring, operation was advised. Instead of a cerebral tumor a circumscribed collection of clear serous fluid was found in the meninges. This having been drained improvement occurred at once and, except for the loss of vision, complete recovery followed. Oppenheim discusses the case and concludes that a hitherto undescribed form of circumscribed serous menin-

gitis of the posterior fossa of the cranium exists, which may develop on the basis of a traumatism or of some other source. Its symptomatology very closely resembles that of cerebral tumor. Definite differential points do not exist. Possibly the presence of symptoms of meningeal irritation, the inclination towards an intermittent course in the progress of the disease and of long remissions in undoubted cases might serve to suggest the presence of the condition. In certain cases the cerebral murmur, which suggests basilar aneurysm, may be present. If the affection does not improve under treatment with mercury and iodide, operation is to be considered. The danger of blindness especially indicates operation. Lumbar puncture may serve to make the condition much worse, whereas radical operation produces a complete cure. Borchardt describes the technique of the operation in Oppenheim's case and reports another similar case.

A Study of the Cammidge Reaction.—Otto Hess discusses Cammidge's reaction for pancreatic disease and comes to the conclusion from his own investigations that it is not specific for pancreatic disease, but that used with care and taken in connection with other symptoms it is of considerable value in diagnosis.

The Question of Serous Expectoration.—Hampeln discusses the serous expectoration which occurs at times after thorocentesis. He says that serous expectoration following pleural puncture may be caused in one of two ways. In a portion of the cases the phenomenon is the result of pulmonary edema, which occurs as the result of aspiration. Its course resembles closely the toxic-neurotic form of pulmonary edema and differs from the more common form. In other cases the serous expectoration is the result of an immediate transit of the exudate from the pleural cavity into the lung parenchyma, an actual expectoration of the exudate. This may occur as a result of a minute perforation or of physiological absorption.

The Treatment of Diseases of the Stomach with Aluminum Silicate.—Rosenheim and Ehrmann have investigated the action of aluminum silicate upon the gastric secretions and upon disease symptoms produced by abnormalities of secretion. They say that in all conditions of stimulated secretion, either hyperacidity or hypersecretion, whether they be primarily of neurological origin or are associated with some organic lesion or injury, aluminum silicate acted as a most favorable drug in reducing the acidity, quieting the pain, and aiding digestion; especially good results were obtained in very persistent hypersecretion, both of the alimentary and persistent form, with more or less persistent motor insufficiency. Objectively the drug caused an inhibition of the secretion energy, a decrease of the hyperacidity, and a reduction of the flow of gastric juice in the empty stomach. There were also cases in which the aluminum silicate caused amelioration of symptoms, when other medicaments, as the alkalis, had been used over a long period with little or no benefit. On several occasions they observed good results with aluminum silicate in general gastric hyperesthesia, depending upon anemia and chlorosis, in persistent paresthesia, in sensory irritability, in cases in which treatment with silver nitrate had been carried out without results. In ulcers of the stomach the acid stimulation due to irritation of the peptic glands was favorably influenced; the rapid cures, however, so often seen when ulcers are treated with large doses of bismuth on an empty stomach, could not be obtained to an equal degree by a similar treatment with aluminum silicate. As a rule, the aluminum silicate was ordered in doses of one-half to one teaspoonful in three ounces of water, three times a day, one half to one hour before meals. Large doses of the drug were always taken willingly, as it is tasteless and odorless. No undesirable symptoms appeared from its use; this was especially true of the intestines. The authors are not willing to say that the salt has no action on the intestines, as it is perfectly possible that the aluminum chloride, which theoretically is formed, may interfere with the development of the bacterial flora. The authors are now carrying out investigations as to the action of the drug on the intestines.

The Treatment of Syphilis in the Light of Recent Investigation.—Lesser discusses the recent advances in diagnosis and treatment of lues, which he summarizes as follows: The discoveries of the transmissibilty of syphilis to animals and of the etiological factor in the disease have so far been of no significance in the actual therapy of human syphilis. On the other hand, the Wassermann reaction serves as an indication for treatment in that it shows us how long the cure should be carried out, and when it should be repeated. The positive serum reaction shows the presence of active spirochete. A negative reaction in the early stage of the disease warrants no conclusions; in the later stage, one can conclude, with a definiteness increasing in proportion to the age of the disease, from a negative reaction, and especially from repeated negative reaction, that the syphilis is cured. One finds in the later stages negative reactions (cures) the more often, the greater number of mercury "cures" have been carried out in the early stage, but with this limitation, that the maximum curative effect is reached with four "cures." For the duration of the cure the amount of mercury must not be considered, but its action, as shown by a negative reaction. Every syphilis treatment must be carried out until a lasting negative reaction is reached.

Treatment of Puerperal Infections.—A. Pinard, from his experience at the Baudeloque and the Lariboisière, gives his conclusions as to the best methods of cure and prophylaxis in puerperal fever. Prophylaxis is much more satisfactory than cure. The first essential is absolute asepsis for every pregnant woman about to begin labor. The toilet begins with a full bath, continues with a toilet of the external genitals with aniodol soap and biniodide of mercury solution 1-4000, and ends with a sterilized pad over the vulva. No vaginal injections are given except when there are fetid lochia, showing infected conditions. As soon as the fetus is expelled a vaginal injection of biniodide is used, and another after the delivery of the placenta; a new vulvar toilet is gone through, and a sterilized pad placed, which is renewed as often as necessary. Every night and morning the external genitals are bathed. All linen used about the patient is sterilized. When patients come in in labor, after examinations have been made, or after the rupture of the membranes has occurred, such patients receive an injection of 40 cubic centimeters of antistreptococcus serum as a preventive measure. This has been found not only perfectly harmless, but very valuable as a prophylactic measure, and for cure of infection. In these women an intrauterine injection is used. In infected cases in which there is thick, bloody, fetid lochia, membranes or placental débris are retained, and here curetting is in order. With normal lochia it is useless; late or too often repeated it is harmful. Intrauterine injections properly used are useful; when not indicated they are harmful. Continuous irrigations are harmful.—*Annales de Gynécologie et d'Obstetrique.*

Infantile Malaria.—Jean P. Cardamatis says that malarial infection is extremely frequent in Greece at all ages, but less so in children under one year of age, probably on account of the habit which mothers have of covering the crib with mosquito netting. In babies under one month of age who nurse their mothers it is extremely rare. The fact of congenital malaria is denied by the author, who has never found the malarial parasite in the blood of such an infant. They are found on the maternal side of the placenta, and a few on the fetal side, but never in the umbilical vein, nor are there anatomical alterations of the placenta in malarial cases. Infants of mothers showing the malarial cachexia are born in florid health. The author believes that parasites cannot be transmitted to the fetus because of some antitoxic substances found in the placenta. Malaria in children may be acute or chronic, and of any type, tertian being most frequent. In infants it is irregular, gastrointestinal and meningeal symptoms being most frequent, and some of the stages being absent. In chronic malaria enlargement of the spleen is immense, and generally present. Anemia is marked, the skin having a waxy hue.—*Annales de Médecine et de Chirurgie Infantiles.*

Extract of Corpus Luteum in Disturbances of Artificial and Physiological Menopause.—Morley reports his results in eighteen cases. The author used an extract made from the corpora lutea of beef ovaries rather than an extract of the entire ovary, as the consensus of opinion seems to be that the internal secretion of the ovary is produced by the yellow body. The extract is given in five-grain doses, three times a day, one-half to one hour before meals. His results in eighteen cases may be summed up as follows: Five were cured, twelve were improved, and one obtained no relief. Included in the twelve cases that were improved are grouped those that are still taking the extract. A permanent cure may result in a few of the cases under treatment. Of the eighteen cases, fourteen suffered from disturbances of operative or artificial and four from those of natural or physiological menopause. While the author says that the results obtained in so small a group of cases do not warrant the drawing of any definite conclusions, still, he thinks that they are favorable enough to justify a continuance of the treatment in other cases, where there is a disturbance incident to artificial or physiological menopause.—*Journal of the Michigan State Medical Society.*

Book Reviews.

A Text-Book of Obstetrics. By Barton Cooke Hirst, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals, etc. Sixth edition, revised and enlarged, with 847 illustrations, 43 of them in colors. Philadelphia and London: W. B. Saunders Company, 1909.

This book was in its earlier editions one of the best known works on the subject in the English language. The present edition has been thoroughly revised and extensively altered, the most important additions having been made in the realm of gynecology, the author including all operations in the most remote way the result of childbirth as belonging to the subject of obstetrics. There have been some changes in the illustrations, several new ones having been added and some old ones discarded. They are as a rule good, but in no way exceptional, giving one the impression that just enough care has been expended upon them to demonstrate the point intended and no more. The text is, however, concise and clear, and gives all that the student needs to know, without going at all extensively into the theory or the pathology of obstetric diseases. As a book to teach the student how to conduct the various stages of labor, their complications and sequelæ, it has attained great popularity, which the present edition will undoubtedly maintain and increase.

Formulaire de Poche pour les Maladies des Enfants. Par le Dr. Jules Comby, Médecin de l'Hopital des Enfants Malades. Troisième édition, entièrement refondue et conforme au Nouveau Codex. Paris: Vigot Frères, 1909.

The third edition of Comby's Pocket Formulary has been made necessary by the advance in pediatric science and by the more recent modification in the French Codex. The arrangement of the work divides it into two parts. In the first, diseases are arranged alphabetically and succinctly and the proper treatment, according to the author's experience, is given, both medicinal and general. Frequently, too, the methods advocated by others are added. In the second part the arrangement is according to drugs. Not only is the dose of each given, with its pharmacological actions, but various prescriptions are added, showing convenient means of administration. The book is neatly gotten up, with a semiflexible leather cover and thin paper.

Modern Materia Medica and Therapeutics. By A. A Stevens, A.M., M.D., Professor of Therapeutics and Clinical Medicine, Woman's Medical College of Pennsylvania; Lecturer on Physical Diagnosis in the University of Pennsylvania; Physician to the Episcopal Hospital and to St. Agnes' Hospital; Assistant Physician to the Philadelphia General Hospital; Fellow of the College of Physicians of Philadelphia, etc. Fifth edition, thoroughly revised in conformity with the eighth revision (1905) of the United States Pharmacopoeia. Philadelphia and London: W. B. Saunders Company, 1909.

The fifth edition of this work has been revised, and contains modifications and additions: the sections dealing with the action and uses of drugs are said to have been largely rewritten. About 500 pages of the volume are devoted to materia medica, and about 150 to therapeutics. The prescriptions are well chosen, and are written without abbreviations. The book should prove useful to students and practitioners.

Food Inspection and Analysis. For the Use of Public Analysts, Health Officers, Sanitary Chemists, and Food Economists. By Albert E. Leach, S.B., Chief of the Denver Food and Drug Inspection Laboratory, Bureau of Chemistry, U. S. Department of Agriculture; formerly Chief Analyst of the Massachusetts State Board of Health. Second edition, revised and enlarged. New York: John Wiley & Sons, 1909.

This elaborate and handsome work is designed chiefly for public analysts and others who are concerned in the carrying out of the provisions of the laws dealing with the suppression of food adulteration. Special attention is therefore given to the nature and extent of adulterations of the various foods, and also to the methods of detecting such adulterants. The general composition of foods and the proximate components of food materials are also dealt with; so, too, are the processes of manufacture of certain foods in cases where impurities might possibly be due to their preparation. The whole subject with which the book deals is one of great importance, which, since the passage of the national pure food law, concerns physicians, hygienists, and scientists more than ever before. The book contains about a thousand large pages, and has chapters on: Food analysis and official control; the laboratory and its equipment; food, its proximate components, its functions, and nutritive value; general analytical methods; the microscope in food analysis; the refractometer; milk and milk products; flesh foods; eggs; cereals and their products; legumes; vegetables and fruits; tea, coffee, and cocoa; spices; edible oils and fats; sugars and saccharine products; alcoholic beverages; vinegar; artificial food colors; food preservatives; artificial sweeteners; flavoring extracts and their substitutes; canned and bottled vegetables, relishes, and fruit products. In addition to numerous tables and illustrations there are forty plates of photomicrographs of pure and adulterated foods and of adulterants. The book seems to be thorough, timely, and authoritative.

A Treatise on Diseases of the Nose, Throat, and Ear. By William Lincoln Ballenger, M.D., Professor of Laryngology, Rhinology, and Otology in the College of Physicians and Surgeons, Chicago. New (second) edition, thoroughly revised. Philadelphia and New York: Lea & Febiger, 1909.

The province of the specialist in diseases of the nose, throat, and ear is widening daily, and is soon destined to imply at least an expert diagnostic and perhaps a therapeutic knowledge also of most diseases of the head and neck. The day is long past when he who wipes out an ear or sprays some more or less inert medicine into the nose and throat can call himself a specialist. Otology necessitates familiarity with the surgery of the brain and of the large vessels in the neck; rhinology is demanding a closer study of diseases of the mouth, such as cancer of the tongue. Cleft palate, too, is becoming the property of the rhinologist. Hence, the physician who now wishes to be considered a thoroughgoing specialist in these things must be a surgeon. In this edition of Dr. Ballenger's book operative surgery holds an important place, and to this end he has introduced many new drawings descriptive of sinus and submucous work, and has revised and enlarged the text very considerably. The clinical application of aural labyrinthine tests now so much under discussion is fully described and illustrated. As the work continues to grow in bulk it will become necessary to divide the subject so that it may fall into two or three volumes. The ear now occupies more than one-third of the 900 pages, diseases of the pharynx and larynx about one-fourth, and the remainder is given up to the nose and accessory sinuses. This work in its present proportions constitutes a combined text-book and atlas upon the nose, throat, and ear. It is not unlikely that a section on stomatology will be demanded later. One may say in truth that it is one of the most comprehensive and helpful books which we have in the field which it covers.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Second Series, Vol. XIV. Q. Rzehak. Washington: Government Printing Office, 1909.

In this latest volume of the invaluable Index Catalogue there are 10,019 author titles, representing 5,281 volumes and 8,158 pamphlets. There are also 31,370 titles of separate journal articles and 4,065 titles of books and pamphlets. In the library there are now 168,879 volumes and 297,560 pamphlets. The librarian is Lieutenant-Colonel Walter D. McCaw of the Medical Corps.

The Blood in Health and Disease. By R. J. M. Buchanan, M.D., F.R.C.P., Professor of Forensic Medicine in the University of Liverpool; Honorary Physician to Out-Patients, Liverpool Royal Infirmary; Formerly Honorary Physician Stanley Hospital, Liverpool; Honorary Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Liverpool. London: Henry Frowde and Hodder & Stoughton, 1909.

This is the newest work on the blood, and it has several characteristics which will insure for it a hearty welcome from students of hematology. In the first place, the illustrations are superb; the colored plates make of the volume a veritable atlas; moreover, these plates represent actual drawings by the author, and are not caricatures. In the next place, the book is written in an attractive style, and both sides of controverted questions are given, with an ample and up-to-date bibliography. Further, it is not only a laboratory manual, but is written from the standpoint of the clinician as well. Many interesting questions are discussed at considerable length; and the arrangement of the subject matter and the methods of technique are alike excellent. The book is of modest dimensions (300 pages of large print), which in conjunction with its pleasing style and good illustrations will secure for it a better chance of being read through than falls to the lot of some books of the kind.

Society Reports

SOUTHERN HEALTH CONFERENCE.

Proceedings of the First Conference to Discuss Hookworm Disease, Held in Atlanta, Ga., January 18 and 19, 1910, under the auspices of the Atlanta Chamber of Commerce and the Georgia State Board of Health.

Dr. H. F. Harris, secretary of the Georgia State Board of Health, was chosen temporary chairman.

History and Zoological Aspect of Hookworm Disease.—Dr. Charles Wardell Stiles of Washington, D. C., stated that the earliest hookworms ever known were described in 1782 by a German clergyman—Geoze, giving to them the German name Haakenwurm. A few years later another German scientist came across numbers of the same group of parasites and used the term "uncinaria." In 1837 Dubini was performing an autopsy in Milan and found in a cadaver a peculiar parasite with which he was not familiar. It proved to be a new species. He called it Ankylostoma duodenale. The first cases of infection with the American species of hookworm which were found were the following: One case observed by Dr. Clayter in a patient from Westmoreland County, Virginia; one case in Galveston, Tex., observed by Dr. Allen J. Smith; several cases in Florida, which were handled by Dr. Guiteras. Personally the speaker had examined about one hundred and thirty cotton mills in the South, and eight milling camps, and in many instances men, women, and children in these mills infected with this disease had it to such an extent that the diagnosis could be made by an expert without the aid of the microscope. Hookworm disease as found in the United States had been traced to the west coast of Africa, and as far as the pigmies of Africa. Unquestionably the negroes must have brought many hookworms to this country. It was an academic question whether the Indians in this country had the disease before the white people came here. Seventy-nine per cent. of the negro farm houses which he had examined and tabulated in North Carolina, South Carolina, Georgia, Alabama, and Mississippi had no privy connected with them. Practically 80 per cent. of the negroes in the rural districts of the South were living under sanitary conditions which were not one iota better than those described for the savage tribes of Africa, and 46 per cent. of the white farm houses he had examined were in no better condition. The distribution of the disease was a natural result of the large negro population, of the unsanitary habits of the people, of the character of the soil and climate. There was probably no disease known in the medical profession which was more easily diagnosed, more easily treated, and more easily prevented than hookworm disease.

Hon. E. E. Rittenhouse of New York City said that this parasite was now sapping the blood and blasting the lives of hundreds of thousands of people. It was causing mental and physical degeneracy and industrial inefficiency; to many of its victims it brought not only physical suffering, but misery and distress from the poverty which it bred. And to this must be added the grief and sorrow that follow the steady march to the grave of those who paid the final penalty for their ignorance of the true cause of their affliction. No department should show more activity and energy than a health department; it should be organized on scientific lines, presided over by scientific men, and provided with a publicity bureau and a large and efficient corps of medical examiners and inspectors and their work should be conducted on a scale consistent with the amount of life waste they were to combat. If practical and permanent assistance was forthcoming from public and private sources, how to live a healthful life, how to guard against and detect disease, would, in the course of time, become matters of common knowledge among the people. A higher standard of life would result and the uplift would be a moral as well as a physical one, for to war against disease and wrong living was to war against poverty, immorality, and crime.

The Pathology of Uncinariasis.—Dr. Newton Evans of Nashville, Tenn., said a very large proportion of all the rural population in the Southern States must have hookworm infection of greater or less severity at some period of their lives. Of 147 men, including both new recruits and those who had been in the army for several years, 64 showed ova of the uncinaria in the feces. All of these were light, not one showing the parasite in the stools and the presence of eosinophilia was absent in a large percentage of the cases. Dr. Evans said with reference to the hemoglobin in Chamberlain's 64 cases, all light and without symptoms, the hemoglobin was from 80 to 100 per cent., with an average of 91.5 per cent. In severe cases the hemoglobin varied from 10 per cent. to 55 per cent. In the severe cases there was a decided reduction of red cells. All observers were agreed that the degree of eosinophilia was not an index of the severity or amount of infection. Poikilocytosis and polychromatophilia were present in the severe cases. The habitation of the worms was usually confined to the upper part of the jejunum and a certain number were found in the duodenum. In a few cases they had been found in the ileum, but never in the colon. The most pronounced change in the liver was fatty degeneration. The changes in the spleen were definite and characteristic. Practically all fatal cases showed a chronic parenchymatous or diffuse nonindurative nephritis. The only constant changes seen in the lungs were the extreme pallor, as in all the other organs and in almost all cases a pulmonary edema. There was cardiac hypertrophy in 10 of 26 cases reported by Sandwith. About the only constant lesions described in the brain were intense anemia and an effusion into the ventricles of a clear, pale, yellow fluid.

The Symptoms of Uncinariasis.—Dr. George Dock of New Orleans said the chief factors that tended to cause uncinariasis or disease phenomena due to hookworm, other than absence of immunity, were early age and poor diet. The disease was most destructive in the young, the greatest amount of sickness and death occurring between 10 and 30 years of age. Mild cases passed imperceptibly out from the latent cases, but when recognized showed a sallow skin, variations in appetite, digestion, and action of the bowels. In the moderate cases pallor and dyspeptic symptoms were more distinct, and often dominated the picture. In the severe cases the anemia, weakness, and dyspepsia were more severe. The abnormalities of the blood were striking and suggestive. The hookworm was the cause of the symptoms directly or indirectly. It must be sought for by searching for its ova, which, even in mild infections, could be found by a brief search.

Treatment of Hookworm Disease.—Dr. H. F. Harris of Atlanta said that on the day before the treatment was to be begun the patient was advised to eat little dinner and no supper at all. Late in the afternoon he was given a full dose of calomel, the amount varying from two to ten grains, depending upon the age and strength of the patient. Castor oil could perhaps be administered with safety, but inasmuch as all oily substances dissolved and made more readily absorbable the thymol which was to be given on the following day,

and as the absorption of any considerable amount of this substance would produce poisonous effects, it was generally thought advisable to leave this drug out of the treatment altogether. If calomel acted freely during the night no other purgative need be administered on the following morning, but if it should not do so a full dose of epsom salts in hot water should be given as soon as the patient awoke. After the bowels had thoroughly acted, finely powdered thymol in capsule was then given, the quantity depending on the age and strength of the patient.

The Educational Campaign Against Hookworm in Texas.—Dr. W. M. Brumby of Austin, Tex., said that recent investigation revealed the infection of 31 per cent. of the male students examined in one of the State Normal Institutes. The bacteriologist had found repeated specimens in twenty-two counties in southern and eastern parts of Texas and those intervening counties being of similar soil, temperature, and climatic conditions, warranting the assertion that every county in Texas east of the 97th degree of longitude and south of the 34th degree of latitude was more or less infected with the hookworm. This section represented fully one-half the population of the State, and portrayed the urgent necessity of persistent and widespread measures for the eradication of this disease in Texas. Their efforts had been limited to educational work, for they recognized the importance of widespread instruction to every locality before they could hope to adopt compulsory measures for the prevention and cure of this disease.

Rev. W. W. Landrum of Louisville said that health was wealth. Those who had health were rich. Those who did not have it were poor, and it was not within the province of many to buy back health when it was once lost. He spoke not for one section of common Christianity, but for all ministers of all subdivisions, the one great creed universal, to tell those present they were deeply interested in this conference, and the clergy would do all in their power to help the medical profession in eradicating this disease from the South.

Dr. Wallace Buttrick of New York stated that he was not a medical practitioner, although in common with the general medical profession he was interested in the welfare of his fellow man, and he took this opportunity to voice not only his feelings and conviction, but gratitude regarding the work of this conference.

Dr. Fred J. Meyer of Jackson, Miss., said that he had frequently thought that of all the monuments that the genius of the ancients erected the greatest was not the pyramids of Egypt, not the colliseum of Rome, not the traditional Colossus of Rhodes, nor the hanging gardens of Babylon, but the cloaca maxima of ancient Rome, which carried off the sewerage of the city in the days of the imperial Cæsars. The main proposition in connection with hookworm disease was to go out and educate the masses in the cause of the prevention of it and to lift by such education the great reproach which lay against the South of constant soil pollution. If this was done he believed in four or five years public opinion would be so educated that legislative bodies would not be appealed to in vain.

Dr. J. J. Kinyoun of Washington, D. C., said that in the uplift which was bound to come through the education of the people against hookworm disease it was going to benefit the whole Southern country, not only with regard to this disease, but with respect to all other communicable diseases. When we conducted anything like a proper and vigorous campaign against hookworm disease then we could eradicate typhoid fever as well from the rural districts. When we got better drainage we would have fewer mosquitoes, and less malaria, and when we eradicated malaria and typhoid fever and hookworm we would find that almost immediately the death rate would be lowered, and we would have two white children to take the place of one at the present time.

Dr. William Weston of Columbia, S. C., said that he had examined quite a number of patients who gave a history of long-standing hookworm infection, and even in those who had reached the ages of eighteen and twenty the epiphyses were not developed. He took occasion to look into the records of these patients in school, as well as those who worked in the mills, and he found they made poor time and their records were not as good in general as other workers.

Dr. F. W. Schnause of Cecil, Ga., said that his observations regarding uncinariasis comprised 849 cases that had been treated during a period of three years. Of this number only nine were colored patients. He gave the reasons for this: The eradication of the disease could be accomplished by education, medication, and legislation. After thoroughly cleaning out the bowel he gave either thymol in capsules or betanaphthol. He had used the thymol like granulated sugar. If it was powdered too fine it would pack in the capsule and pass through the bowel very rapidly. He liked betanaphthol because it was not so pungent, and did not need to be given in quite as large a dose, although he gave large doses, 100 grains or more in three doses, two hours apart, and used enemata if the bowels did not move rapidly enough.

Dr. A. G. Fort of Lumpkin, Ga., said he had had the opportunity of studying hookworm disease, diagnosed and treated about 600 cases, and in a measure had estimated the percentage of inhabitants who were victims. As to the ways and means, he said that we should, first, interest the profession throughout the infected areas, and demonstrate to them the means of diagnosis and the value of treatment. If all sections were alike with reference to this matter the percentage of doctors treating the hookworm disease was quite small, about one doctor to every 10,000 people. Second, we should interest the school authorities and have every pupil examined and treated. Attention should be called to the means of infection and the children protected by the sanitation of the school room. Third, we should interest the people from an economic standpoint, and particularly the men who employ in their mills, factories, and farms these people. Fourth, means of treatment should be provided for the poor, and an effort should be made to see that the people are educated as to its danger, and the benefits to be derived from treatment and means of prevention pointed out. When this was done we could hope for great results from this crusade.

Dr. C. C. Bass of New Orleans discussed some of the difficulties in the diagnosis of mild hookworm infection. In well-marked hookworm infection the clinical evidence, blood findings, and history of the patient were usually sufficient to direct an observer familiar with the disease to a correct diagnosis. A very simple examination of the feces in such cases would settle the diagnosis. Recently a section, numbering 56, of a class of students in the Tulane Medical College were examined and 21, or 38 per cent., found infected with hookworm disease. In several instances the infected ones appeared as healthy as many of those not infected. It would have been impossible to pick out from appearance the infected men. Careful weighing and measuring showed that the infected averaged 142 pounds, the uninfected 150½ pounds. Not only did

appearance fail to reveal the presence of anemia in the infected students, but estimation of the hemoglobin of each by five or more men showed an average of 90 per cent. for the infected. All denied having had ground itch within seven years, and a few of the infected claimed never to have seen it. Whether uncinaria lived and continued to menace the patients long after they cease to lay eggs might have an important clinical bearing on the subject, for if they did an explanation would be offered of the cases who failed to regain normal health and blood after treatment or removal from the source of infection. Recently he carefully dissected a collection of 247 females of *Uncinaria americana* and found that 18, or 7 per cent., of the adult worms contained no eggs. Egg-laying animals higher in the scale laid few or no eggs in the last third of their lives, and it was probable that the same thing applied. to some extent at least, to these worms. Other observers should study available specimens with this point in view and report their observations.

Dr. H. G. Perry of Greensboro, Ala., said that in more than 100 cases of uncinariasis of which he had record there was only one mulatto and not a single pure-blooded negro. He had to report also that all of these cases occurred among those living on sandy soil. Eighty-five per cent. of his cases were pronounced cured and the remaining were greatly benefited, and doubtless would have been completely relieved had the treatment been persisted in. Improvement could be easily demonstrated by the passage of the worms, by the certain and gradual rise in the hemoglobin, and by an increase in weight.

Preservation of Man.—Dr. R. M. Cunningham of Birmingham, Ala., said that this was not a question for the rich or poor, but a question for all. First, there was a part to be played by the medical profession; we were the investigators, the pioneers, the discoverers. Our province was science; our method was art; our motto was the eclectic, and our purpose was truth. We recognized but one great democracy, that of science, and but one autocrat, that of truth. No school of scientists, nor organization of men, was doing more for the human race, inspired by the love of science and the love of their fellow men, than that of the medical profession. The time would come when the vacant lands would all be taken up and when the most aggressive races would conquer the less aggressive. The white races, the Caucassian races, in a hundred thousand years would become the supreme masters of the world. Then they would begin war on each other, and that nation which among the commonwealths of nations had stood for man in body and in mind would go forth as the ancient Spartan, inspired not merely with patriotism, but with the spirit and genius to fight and to maintain. Take the history of the whole civilized world. Take the ancient Babylonians, the Egyptians, or the ancient Grecians, or take the civilizations of Spain, Italy, and France, and it had been the history of the world that that nation which stood for man, his physical, moral, and mental potency, was the nation in the end that would triumph over the rest of the world and maintain its autonomy forever.

Biology of the Hookworm.—Dr. Charles Wardell Stiles of Washington, D. C., stated with reference to soil pollution that during his investigations he had examined something like 20,000 toilet closets, and that this was a fair representation of the average sanitary condition to be found on the farm, soil pollution occurring all around, spread by the chickens and the hogs. Sixty-eight or more per cent. of the farm houses he had tabulated in North Carolina, South Carolina, Georgia, and Alabama had no toilet of any kind whatsoever. Was it any wonder that we had a high typhoid death rate, and widespread hookworm disease? Of the negro farms 79.8 per cent., so far as he had been able to tabulate them, had no toilet, and of the white farm houses about 46 per cent. had no toilet. These figures might seem astounding, and yet what did Dr. Brumby say this morning about Texas? On examination of 100 houses, toilets were found in only five. What was the solution of this problem? The institution of the sanitary toilet with the tub system and a fluid disinfectant. This would cut the typhoid death rate of the South in two. It would almost eradicate hookworm disease. It would almost eradicate Cochin-China diarrhea, amebic dysentery, and various other intestinal infections.

Dr. B. B. Bagby of West Point, Va., said he thought they had as many cases of hookworm disease in Virginia as they had in Georgia. In examining the stools of patients in his district he did not hesitate to say that fully 80 per cent. of the people who worked in the cotton mills in Virginia were infected with hookworm. In almost every case of old-fashioned foot itch he had found hookworms in the intestines.

Dr. Jere L. Crook of Jackson, Tenn., asked Dr. Stiles whether it was justifiable in the present light of our knowledge to administer thymol on a tentative diagnosis, or whether it was necessary to have the microscopic findings before so doing.

Dr. Stiles said that any physician in the South could forward fecal material to the State Board of Health, or to him at Washington, and it would be examined free of charge, and the physician informed of the results of the examination by return mail. If, for any reason, a microscopic examination was not feasible, personally he would not hesitate to give experimentally thymol treatment, unless it was contraindicated by the patient's condition. He would not give it in a case of pregnancy, nor in a case of severe cardiac symptoms.

Dr. Claude A. Smith of Atlanta said that when it was his fortune in 1901 to discover the first case of hookworm disease which they had in Georgia, he did not realize the extent of the malady. He immediately began an investigation and through the assistance of Dr. Green examined 20 convicts, who worked in clay, and they found two additional cases. The first case occurring in a mulatto came to autopsy. In the two additional cases the infection was mild. He began to investigate the mode of infection, and became convinced that it was through the skin. This was confirmed clinically by many cases. From one man he recovered 1,300 parasites. He had demonstrated repeatedly that the disease was contracted by the parasite passing through the skin. Since then his investigations had convinced him more thoroughly than ever that it was the principal mode of infection.

Dr. A. G. Fort of Lumpkin, Ga., stated with reference to the treatment of hookworm disease that thymol was the standby; but the use of betanaphthol took the place of thymol very well, and it could be given in powder form, and patients did not object to it as they sometimes did to thymol.

Dr. Edward E. Lindeman of Tampa, Fla., said that quite recently there were sent to the State Board of Health of Florida several specimens of what appeared to be calculi accompanying the pathological condition of uncinariasis, but upon microscopic examination of the crystals and chemical analysis they proved to be solid masses of thymol. It was quite evident from this that thymol would pass through the intestinal tract at times in a solid mass, and therefore thymol in a solid mass had no therapeutic value. The manner in which thymol acted prompted him to look into the matter

a little to see in what form thymol might be administered to the best advantage. Thymol acted upon the parasite by the crystals, in a fine condition, coming in contact with it. Thymol in solution, however, had little or no therapeutic value, although thymol in a finely suspended state had. It was desirable that the thymol be given in a finely powdered state, so that it would become widely disseminated and the crystals come in contact with the worms.

A permanent organization was formed and is to be known as "Southern Health Conference." The following officers were elected: *President,* Dr. H. F. Harris of Atlanta, Ga.; *Secretary,* Mr. W. G. Cooper of Atlanta, Ga.; *Vice-Presidents*: Alabama, Dr. H. G. Perry of Greensboro; Florida, Dr. Hiram Byrd of Jacksonville; Georgia, Mr. Wilmer L. Moore of Atlanta; Kentucky, Dr. J. B. Marvin of Louisville; Tennessee, Dr. J. A. Albright of Nashville; Virginia, Dr. E. G. Williams of Richmond; North Carolina, Dr. R. H. Lewis of Raleigh; Mississippi, Dr. S. H. McLean of Jackson; Arkansas, Dr. E. H. Martin of Hot Springs; South Carolina, Dr. William Weston of Columbia; Texas, Dr. W. M. Brumby of Austin; Louisiana, Dr. George Dock of New Orleans; District of Columbia, Dr. William C. Woodward of Washington; Oklahoma, Dr. J. L. Shuler of Durant; United States Army, Major B. D. Taylor of Atlanta; United States Navy, Past Assistant Surgeon J. H. White of Washington; Hawaii, Dr. W. D. Baldwin of Honolulu.

Vital Statistics.—The following resolution was adopted: *Whereas,* It is exceedingly difficult to get accurate information concerning health conditions in the South, except in a few localities; therefore, be it *Resolved,* That the executive committee, the president, and vice-president, and the board of councillors for each State are requested to bring to the attention of all State and municipal legislatures the urgent need for providing some efficient measure for the uniform collection of vital statistics, such as the bill which has been approved by the American Medical Association and the United States Government.

National Bureau of Health.—The following resolutions were adopted: *Resolved,* That this conference memorialize Congress and the President of the United States on the subject of a National Bureau of Public Health, and that a special committee be appointed to present this matter at Washington. Be it further *Resolved,* That members of the conference in their respective communities, and the vice-president and the board of councillors in each State are requested to use their influence with the members of Congress for the establishment of such a department.

Dr. W. F. Westmoreland of Atlanta offered the following resolution, which was adopted: *Resolved,* That the Southern Health Conference by a rising vote extend to Mr. Rockefeller its sincere thanks and high appreciation of his munificent and humanitarian gift to our people to aid them in the arrest and cure of hookworm disease.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 6, 1910.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Ophthalmology.

The Best Methods for the Diagnosis and Treatment of Ocular Tuberculosis.—Dr. George S. Derby of Boston read this paper. He confined his remarks to tuberculosis of the anterior part of the eyeball. The introduction of the subcutaneous tuberculin test widened their diagnostic field and proved that the clinical appearances of the disease were not so readily recognized as had hitherto been believed. The increasing interest in general tuberculosis led to the introduction of the new local tuberculin tests and the diagnosis again appeared easy. Experience soon showed, however, that a very considerable proportion of all people healthy or otherwise reacted to these new tests, and to the older subcutaneous test. As a result they were again in the negative phase. The first question which came up was: What evidence must they have in order to make a definite diagnosis of tuberculosis of the eye? He knew of but two by which a definite diagnosis might be made. First, by the microscope, and this method was available practically only in cases of conjunctival tuberculosis. Out of the last 70 or 80 cases that he had seen, it was possible to make the diagnosis only twice in this manner. Secondly, by the production of a local reaction in the eye following a subcutaneous injection of tuberculin. This method had its limitations. It should be borne in mind that a positive test with its unpleasant symptoms had at times a profoundly depressing effect on the patient. A local reaction in the eye might retard considerably the patient's progress. A very considerable proportion of cases did not show the desired local reaction; the general reaction obtained was little more valuable as evidence than was a positive cutaneous reaction. He withheld the subcutaneous test until all other methods had been exhausted. Of the less conclusive tests for the diagnosis of tuberculosis of the eye, the Pirquet was valuable for the negative information it furnished. Their rule had been to exclude tuberculosis on the evidence of two negative cutaneous reactions performed with 100 per cent. old tuberculin. In a small percentage of adults, however, they had to admit that this test was uncertain. The clinical picture was, of course, of great importance in the diagnosis. If they left out of consideration the ordinary phlyctenular type of the disease they might find in the conjunctiva the vegetations and ulcers which had so long been recognized. These were nearly always situated on the palpebral conjunctiva. In addition there might be the well known large phlyctenulæ usually seen in adults, and situated at a little distance from the cornea. This might disappear entirely or be gradually replaced by a scleritic nodule. In addition there might be the little grayish yellow raised structures occurring frequently in scleritis. Personally he believed that a large proportion of all scleritis was tuberculous. Certain appearances in tuberculosis of the cornea were characteristic, such as the rounded yellow or gray nodules occurring singly or in groups, situated deeply and vascularized at some period of their development. In his experience the classical interstitial keratitis was seldom of tuberculous origin. The tuberculous type of the disease presented varied and atypical features. A very typical feature was the nodule developing in the iris angle and up over the posterior surface of the cornea, starting at the lowest part of the cornea and leaving a very characteristic triangular scar with its base downwards. Tuberculous iritis usually started like an ordinary iritis and only later might nodules develop. These might be situated at any point in the membrane. What was very noticeable about all these cases was the frequency with which the clinical picture changed from day to day and week to week. The disease jumped from the sclera to the cornea, cornea to iris, iris to sclera, or *vice versa.* In most severe cases all three membranes were likely to be affected at some period of the disease. Corneal processes showed more tendency to remain localized, however, than did those in the sclera or iris. In certain forms of ocular tuberculosis the clinical appearance was of great assistance in making the diagnosis, while in other forms it might be of no help whatsoever. Of 26 cases reported last year, 19.2 per cent. gave a bad family history, while in another series of 34 cases, 20.5 per cent. gave a bad family history.

Tuberculosis of the eye was essentially a recurring disease and he believed that if they questioned these patients carefully they could usually get a history of previous inflammation. In their series this year they got such a history in 58 per cent. of the cases. If accident and blenorrhea neonatorum could be ruled out, he believed that the presence of corneal scars in childhood usually pointed toward a previous tuberculous infection. In this connection he said it would be interesting to learn in what proportion of cases with tuberculosis of the lungs, joints, glands, etc., corneal scars occurred or a history of ocular inflammation in childhood could be obtained. During the past autumn he examined 250 patients at the Massachusetts State Sanatorium with this in mind and found only two positive cases. Although various writers stated that comparatively few cases of ocular tuberculosis presented physical signs outside the eye, his experience had been the reverse. In the series of cases presenting deep tuberculous lesions of the eye, 69 per cent. gave suspicious signs of tuberculosis elsewhere. The diagnosis of ocular tuberculosis could seldom be made on any one point alone, but must be built up from all the facts in their possession. One year ago a tuberculosis class was established at the Massachusetts Charitable Eye and Ear Infirmary and Dr. Derby told of their system of handling these cases there. Their personnel consisted of an ophthalmologist, an internist, a social worker, and a nurse. During active ocular inflammation or increased temperature they insisted on complete rest. The patients were instructed as to diet and fresh air and were shown personally how they might rest out of doors. To his mind this was the most uncertain disease which they treated. In their experience there was no ratio between the severity of the disease and the general condition of the patient. They were inclined to look askance at a tuberculous eye occurring in a person of excellent physique. They had handled some 50 cases during the past year and a number of cases in preceding years and had never yet had to resort to the removal of an eye. Some of these patients relapsed in the most unaccountable manner. He believed there was a crying need for a small ward in each eye hospital for these cases who did not get proper care at home. They used tuberculin on nearly all of their cases. They aimed to give as large a dose as the patient would stand without any sign of a reaction, local or general. They began with 1-10,000 of a milligram and worked up with reasonable speed, seldom going above 1 mgm. Tuberculin was not given at the menstrual period. They believed in continuing the tuberculin after the ocular process was well.

Tuberculosis of the Conjunctiva.—Dr. Carl Koller presented this patient, an apparently healthy young man, 21 years old, without any signs of pulmonary tuberculosis. For about two months before being referred to him the patient had been treated by his family physician for an affection of the lower lid, which looked like an "infarct of a Meibomian gland." There were three inflamed chalazea of small size in the tarsus of the upper lid, the cutis of which showed considerable venous congestion. The affection on the lower lid presented itself as a small wedge near the free edge of the tarsus, intensely red, neither ulcerated nor raised over the conjunctival surface of the tarsus, but protruding over the free edge of the tarsus like a pouting lip. With a strong loupe the smallest nodules could be seen beneath the surface between the ducts of the Meibomian glands on both sides of the wedge-shaped formation. A small portion of the latter was excised and under the microscope typical young tubercles were shown imbedded in tissue, presenting the appearance of reactive inflammation (most likely the effect of former cauterization). Similar nodules could be discerned with the loupe on a spot of the tarsal conjunctiva of the upper lid situated over one of the three suppurating small chalazea. This patient had been treated without tuberculin injections, but with frequent scarifications and application of nitrate of silver solutions of varying strengths with most excellent results.

Etiology of Scleritis; Its Treatment and Results with Tuberculin.—Dr. Ervin Török said that scleritis was a well known disease and yet one of the rarer diseases of the eyeball. In his experience in the eye-clinic of the University at Budapest in the year 1905, only 35 cases out of 11,380 (0.30 per cent.) were of this nature, and at the New York Ophthalmic and Aural Institute in 1907 there was recorded a percentage of 0.28. The clinical picture presented itself as follows: There was a more or less circumscribed bluish-red, or often violet, nodule in the anterior part of the eyeball between the limbus and the equator, usually projecting above the level of the sclera, forming a small elevation the size of a pepper seed. The conjunctiva was edematous and swollen with enlarged blood vessels. There was ciliary injection around the nodules and episcleral veins. The conjunctiva was movable above the sclera and the redness disappeared for a short time under pressure. The nodules would be absent in some cases, but the characteristic bluish-violet injection in a large area was always present. There were yellowish elevations around the scleritic nodule, usually situated in the vicinity of the blood vessels and they were similar to tubercles. The subjective symptoms complained of by the patients varied. Some would complain of a mild degree of photophobia and epiphora; others of a severe pain in the eye and the bony surroundings of the eyeball. The pains usually disappeared first, then the nodule, and then the injection; a circumscribed grayish scar was left. The majority of the cases were chronic, and relapses were prone to occur, usually lasting over several years. The most common complication was the involvement of the cornea, an infiltration in its adjacent parts which did not absorb, but caused a permanent, deep, bluish-white opaque spot. Other complications were cyclitis, opacities of the vitreous with increased tension which impaired vision. In the beginning it was usually limited to one eye, but in its course it usually involved the other. Scleritis might occur at any age, but they found it more often in adults, and chiefly in women. The etiology was unknown. Vossius claimed that it was due to chronic rheumatism, gout, or menstrual disorders, but rarely to scrofula or lues. Fuchs found that his patients were affected with scrofula, tuberculosis, or hereditary lues, and admitted menstrual disorders as a factor. Nichel's claim was based on some general diseases, various forms of joint rheumatism, with serous inflammations of the joints, but with no elevation of temperature. Many cases of scleritis were due to gout, but the larger percentage of the cases were either syphilitic or tuberculous. Alt said that rheumatism, gout, syphilis, and tuberculosis were the causative factors. Swanzy claimed that it was due to congenital syphilis, rheumatism, gout, goiter, and menstrual disorders. Posey and Wright agreed upon gout and rheumatism as the cause in most of the cases, but when no such history was found they believed that the various disturbances of digestion were causative. Panas said that rheumatism, gout, menstrual disorders, scrofula, and congenital syphilis were among the causes. However, all authors agreed upon one point, connecting scleritis with some disease of the body. The most prominent of these were rheumatism, both of the joints and muscular system, gout, syphilis, both congenital and acquired, disturbances of menstruation and digestion, gonorrhea, malaria, scrofula, while some mentioned tuberculosis as a possible cause. All the authors found the scleritic nodules to be composed of round and epithelioid cells. From all the published reports the pathological examination gave the picture of an inflammation without any characteristic signs from which they might deduce

the cause. The only exceptions were Zimmermann's case and four cases of Verhoeff's which showed typical tuberculous structure. Dr. Török said that a few years ago he looked for tuberculous disease of the eye and applied the tuberculin treatment, with the remarkable result that he learned that tuberculous disease of the eye was more often met with than the reports and statistics so far had recorded. He found it most frequently in deep scleritis, and these were the cases where the cornea, iris, and ciliary body were involved. In preparing his paper he said he had studied clinically the action of tuberculin upon cases of scleritis and within the last five years all these cases, so far as was possible for diagnostic purposes, were subjected to Koch's tuberculin, and for therapeutic purposes the cases were subjected to T. R. The end result of the research in his opinion was, that tuberculosis was the main and most probably the only etiological factor. Several authorities had spoken in favor of this hypothesis, while others had spoken against it. The claims of those who spoke against the tuberculous origin were based upon the following: (1) Inoculations of excised nodules into rabbits failed to develop tuberculosis. This could be disproven because positive results proved the presence of tuberculosis which negative results did not disprove. (2) The lack of the characteristic microscopial picture of tuberculosis and the absence of the tubercle bacilli. This statement was disproved by the knowledge that the pathological picture of tuberculosis varied; they could not disprove this diagnosis; they could not make it dependent upon the microscopical picture. Such cases were cited by Mitvalsky and Rhein. Some authors mentioned tuberculosis as an etiological factor only as a rare and probable one. Thirteen cases of Verhoeff's reacted upon Koch's old tuberculin; the subsequent treatment of these cases showed great improvement in some instances, and complete recovery in others. Dr. Török gave the record of fifteen cases, three males and twelve females. Four were between the ages of ten and twenty; six between twenty and thirty; five between thirty and fifty. The family history showed tuberculosis in four cases; tuberculosis was suspected in two cases; there was a negative history in nine cases. Five patients suffered from tuberculosis; there were no evidences of the disease in the other ten. They all suffered from scleritis in chronic form lasting from three months to four years. Thirteen cases showed corneal complications; two cases showed involvement of the sclera only, one being an episcleritis. Six out of the thirteen cases showed an iritis. T. V. was administered in fourteen cases; twelve of these gave a positive reaction. Local reaction was noticeable in the increase of the injection, with photophia and pain and, in some cases, the development of new small nodules. In certain cases the conjunctiva also participated; the eyelids became edematous, the conjunctiva became red, swollen, succulent and there was a free mucopurulent secretion. Conjunctival involvement disappeared without treatment in a few days. One case subject to acute articular rheumatism would not submit to the tuberculin test; he showed improvement under salicylate of soda, but relapse was observed four months later. T. R. was administered in 11 cases with the following results: Ten cases were cured in from eight months to four years without relapse; one case showed considerable improvement after eleven injections of T. R., but the final result could not be obtained as the patient failed to report. In spite of the negative result of the T. V. injection. T. R. was administered in two cases with perfect recovery. Three patients with positive T. V. reaction would not submit themselves to treatment. The author stated that tuberculosis was the most frequent and probably the only etiological factor in scleritis. Episcleritis might be due to rheumatism. Typical gelatinous scleritis was never due to lues. Syphilis in the tertiary stage might produce a gumma of the sclera, or a papule in the secondary stage. Both might resemble true scleritis, but would never have the typical symptoms and course of such. Great emphasis must be laid on the true family history and thorough examination of the patient in every case of scleritis. Every case of scleritis should be injected with T. V. and in case of positive reaction the administration of tuberculin should be applied. Even in cases where T. V. failed to give a positive reaction tuberculin injections should be administered.

Dr. Emil Gruening, in opening the discussion, said that upon the whole cases affecting the anterior half of the globe were but rarely due to tuberculosis. It has been said by one of the speakers of the evening that, in his opinion, and in that of others, scleritis was invariably due to tuberculosis. From this assertion he wished to dissent. Scleritis might, in rare cases, be due to tuberculosis, but ordinarily it was due to other causes. They had scleritis long before they had become acquainted with tuberculin injections, and even the recurrent cases of scleritis yielded to aspiring and warm applications. If it were maintained that scleritis was due to tuberculosis, we must hold that for its cure tuberculin was unnecessary. Parenchymatous keratitis might in some rare instances also be due to the presence of tubercles, but in the vast majority of cases that one saw in our clinical material the disease was indubitably due to inherited syphilis, and yielded to the local treatment of dionin, atropin, and warm applications, and the general treatment of iodide of potassium and mercury. In conclusion Dr. Gruening wished to thank the guest of the evening, Dr. Derby, for his instructive communication.

Dr. Charles Stedman Bull, in discussing Dr. Derby's paper, considered the points upon which they might base their diagnosis. It was a well recognized fact that the ocular lesion might be primary and that it might be the only existing focus of the infection in the organism. It was known that when the lesion spread from the interior to the exterior of the eyeball, the foci of disease might always be found in the filtration angle. The presence of indurated glands was not pathognomonic, but of great diagnostic value. They knew from Mr. Treacher Collins that the reaction of the tissues to the various tuberculin tests consisted of an aggregation of cells made up of a central giant cell, the so-called Langhans cell, epithelioid cells, and lymphocytes. The three conditions, cellular aggregation, the giant cell system, and caseous degeneration when found together in a tissue made the diagnosis of tuberculosis practically certain. A failure to find the tubercle bacillus after careful search did not disprove the tuberculous nature of a lesion. Reactions from tuberculin tests were of three varieties: The local reaction at the point of puncture, which was slight and delicate; the ocular reaction, which should be unmistakable, and the general or constitutional reaction. Dr. Bull said that he had abandoned the conjunctival test as he considered it liable to cause a most obstinate and severe conjunctivitis in a perfectly healthy eye. The examination of eye cases for suspected tuberculosis should be conducted as follows: (1) A thorough physical examination of the nose, throat, lungs, joints, etc. (2) A careful statement of the existing disease condition of the affected eye. (3) The examination with tuberculin as follows: (*a*) The cutaneous test should be made by rubbing one drop of old tuberculin into two scarified points on the arm about 5 cm. apart. For a control one drop of a one-half per cent. carbolic-glycerin solution should be gently rubbed into a scarified point between and a little to one side of the line of the other two points. The scarified points need not be more than one-half inch in diameter; care should be taken not to draw blood, but to see that serum exuded. The case should be personally examined within the first twenty-four hours and the

time when the reaction first appeared should be noted. The size of the areola should be measured in millimeters and the intensity of the reaction noted. The vaccination points should be examined 24 and 72 hours after the test. (*b*) In case the conjunctival test was made, the degree of conjunctival reaction should be noticed within twelve hours and a careful record kept of its character and duration. If both these tests were negative they should be repeated in the same manner after four days. If these tests again proved negative and clinical evidence pointed to tuberculosis, the subcutaneous test should be applied. (*c*) In making the subcutaneous test the temperature should be taken every two hours for two days prior to the injection. If it was found to be normal the test might be made according to Koch's method, with an injection of one mg. of old tuberculin. If the result was negative at the end of three days, 3 mg. might be used. If the result was still negative a dose of 5 mg. might be used at the end of three days. If this was negative it might be assumed that active tuberculosis did not exist. If the result was positive, a record of the temperature should be made every two hours and the character of the reaction described. Both the eye and the point of puncture should be carefully watched for reaction. In reference to the employment of tuberculin as a therapeutic measure, Dr. Bull said that he had used O. T. of Koch, T. R., and two other preparations, one a 50 per cent. solution of tuberculin and the other the original tuberculin T. O., prepared after the method of Koch, and he preferred the latter. The tuberculin excited a reactive inflammation in the surrounding tissues, and this result was best obtained by the use of small, gradually increasing doses. Relapses were frequent, but occurred less frequently if treatment was carried out for months. Beginning with a dose of 2 mg. the strength of the injection might be gradually increased to 5 mg. Injections were given on alternate days for three weeks, then twice a week for three weeks; then once a week for as long as might be necessary. Many cases were obstinate in resisting treatment, but most of them were benefited and some were apparently cured.

Dr. John E. Weeks congratulated Dr. Derby upon having the method adopted at the Massachusetts State Sanatorium which had been so productive of good results. With regard to the diagnosis of tuberculosis of the eye he wished to endorse what had been said so far as the use of tuberculin was concerned; that was, they must have a local reaction in the eye before stating positively that tuberculosis of the eye existed. He had employed the skin reaction and the conjunctival reaction; he did not consider either of great value for the reason that if one got a reaction by either method, it did not prove that the condition of the eye was tuberculous. It simply went to show that there was a tuberculous focus somewhere in the body. At autopsies a very large percentage of the cases examined had some focus of tuberculosis from which they had recovered. Among the methods employed in making a diagnosis was that of inspection. Tuberculosis of the conjunctiva presented two principal forms. First, acute miliary tuberculosis. Anyone who had observed the results of inoculation of the conjunctiva with tubercle bacilli would be able to recognize the condition readily. The tubercles developed rapidly on the ocular conjunctiva as well as on the palpebral conjunctiva. They resembled trachoma granules. Second, there was a chronic form of tuberculosis of the eye which resembled lupus. This was a condition of localized superficial ulceration of the conjunctiva with ragged borders. In tuberculosis of the eyeball, cornea and sclera present characteristic appearances in the isolated grayish foci; when these are present, it means that the condition in the sclera was invariably due to tuberculosis. There were many cases of scleritis which presented clinical appearances which did not correspond to the inflammation caused by the tubercle bacilli. Scleritis could be caused to disappear under treatment not connected with the treatment of tuberculosis as, for instance, sodium salicylate. Dr. Weeks had recently seen a case of scleritis of more than two years' duration which did not present the grayish foci peculiar to tuberculous scleritis. All symptoms entirely disappeared under the use of sodium salicylate. Another method of diagnosis, already alluded to, was the microscopical examination. Another, the inoculation method. One was not always able to demonstrate the tubercle bacillus in tuberculous tissue under the microscope. In such cases the introduction of a piece of tissue into the anterior chamber of a rabbit would produce a tuberculous iritis in three or four weeks. Another method of diagnosis was by exclusion. One might observe a growth in the iris, sclera, or some other part of the eye and suspect it to be tuberculous, but might not be able to determine it either by inoculation or inspection. If in these cases a negative effect is obtained by the use of the iodides, mercury, and the salicylates, in the absence of symptoms which pointed definitely to a malignant growth, one might be warranted in stating with some degree of certainty that the condition was tuberculous. With regard to the use of tuberculin for diagnostic purpose, Dr. Weeks quoted from a paper read by Dr. Trudeau at Washington some years ago in which was outlined the method of making a diagnosis of tuberculosis by subcutaneous injection, as follows: "The range of the patient's temperature is ascertained by taking it at 8 A. M., 3 P. M., and 8 P. M., for three days before making the test. The first injection should not exceed 0.5 mg., and if any fever is habitually present should even be less, and is best given early in the morning or late at night, as the typical reaction usually begins, in my experience, within six to twelve hours. Such a small dose, while it will often be sufficient to produce the looked-for rise of temperature, has under my observation never produced unpleasant or violent symptoms. An interval of two or three days should be allowed between each of the two or three subsequent injections it may be necessary to give, as reaction in very rare cases may be delayed for twenty-four or even thirty-six hours. On the third day a second dose of 1 mg. is given, and, if no effect is produced, a third dose, of 2 mg., three days later. In the great majority of cases of latent tuberculosis an appreciable reaction will be produced by the time a dose of 2 mg. has been reached. If no effect has been caused by the tests applied as above, I have usually gone no farther and concluded that no tuberculous process was present. If some slight symptoms, however, have been produced by a dose of 2 mg., it may be necessary to give a fourth injection of 3 mg. in order to reach a positive conclusion. Nevertheless, it should be borne in mind that in a few cases the exhibition of even larger doses may cause reaction, when the smaller do not, and indicate the existence of some slight latent tuberculous lesion, and the negative result should not, when applied within the moderate dose described, be considered absolutely infallible. No evidence in connection with the tuberculin test as applied to man and animals has been forthcoming thus far from those who have made use of it, which would tend to sustain the general impression that this method is necessarily dangerous and tends invariably to aggravate the disease, and my own experience has developed nothing which would seem to confirm this impression." With regard to the treatment, Dr. Weeks called attention to the efficiency of the various preparations of tuberculin. He has used tuberculin prepared by the Health Board of New York City to some extent. He had found it excellent for diagnostic purposes and although it was heated to 70° or 80° C. in the process of preparation, it had therapeutic value as well. The new tuberculin of Koch was not heated to such a degree. Its therapeutic value was probably

greater than the old tuberculin (T. O.). The method employed by Von Hippel for therapeusis was advised. The dose given should be just short of a sufficient quantity to produce reaction. Von Hippel began with 0.05 mg. and gradually increases the dose. Another form of tuberculin that was valuable and probably more active than the T. R. was the so-called bouillon filtré, B. F. of Denys. This was given in about the same dose as the other, and the same results were obtained as with the T. R. In Dr. Weeks's experience tuberculosis of the eye was not so extremely common. Within three years he had treated eleven cases. Of these eleven there was one case of tuberculosis of the iris, four of the choroid, three of the cornea, and three of the sclera and cornea. In all of these cases he obtained a local reaction. The therapeutic results of the treatment with tuberculin in all the cases had been satisfactory.

Dr. Wilbur B. Marple said that although he had used tuberculin rather extensively as a diagnostic aid in various ocular lesions as to the etiology of which he was in doubt, the results had been in most cases negative. In two cases, however, during the past year the results so far as treatment was concerned were very satisfactory. From the consideration of this not very abundant material he had reached some conclusions which were in harmony with those of others with larger experience and which were given below. One of his cases was of considerable interest and he gave briefly her story. The patient was a young colored girl, aged twenty-two, of good general health, with no evidence of tuberculosis elsewhere. She was seen first early in January, 1908, and the diagnosis of keratoiritis of the left eye was made, and she was put on specific treatment. The condition grew steadily worse, and, after two or three weeks, disseminated nodules began to appear in the iris. On February 3, 1908, the condition presented the appearance shown in the drawing by his assistant, Dr. George Young. January 30 she received 1 c.c. of old tuberculin = 1 mg. hypodermically for diagnostic purposes. There was no reaction, either local or general. February 4, she received the same dose. February 5, 0.5 c.c., 9, 2 c.c., 13, 4 c.c., and 17, 3 c.c. On one occasion she had an evening temperature of 99°, the nearest approach to a reaction she had at any time. But though there was no local or constitutional reaction, the appearance of the eye during these three weeks while she received tuberculin injections underwent a remarkable change, which was shown most excellently by a series of pencil sketches, also by Dr. Young. On January 27 there were numerous disseminate tubercles in the iris with exudate on Descemet's membrane. Intense pericorneal injection. Pupil dilated imperfectly with atropine. It gradually dilated until it was dilated *ad maximum*, except below, on February 23. The pericorneal injection gradually disappeared, the exudate lessened, but the most striking change was the disappearance of the tubercles, none being visible on March 2, the date of the discharge. On admission her vision was fingers at 10 feet, on discharge, March 2, it was 20/70. In this case injections of old tuberculin were employed for diagnostic purposes. Not getting any reaction they were repeated over a period of a little less than three weeks with the surprising and unexpected improvement in the patient's condition described above. The patient disappeared and was not seen again until April 16, six weeks subsequently. There were then again numerous mutton fat exudates over the lower half of Descemet's membrane and several tubercles in the iris and vision was fingers at 15 feet. She was then put on T. R., 1/500 mg. hypodermically every three days, increasing the dose 1/500 mg. each time. May 18, there were no tubercles in the iris, the exudates were less, and the eye was much whiter. The details of the fundus could be seen. L. V. = 20/70 with 1.5 D. of hyperopia corrected. She left the city in June and her treatment was continued by a colleague until the end of September. Dr. Marple concluded as follows: 1. For diagnostic purposes begin with very small doses and increase slowly, thus avoiding excessive reactions. He had begun with 1 mg. of old tuberculin subcutaneously and increased gradually up to 3 or 4 mg. or more. No reaction following, he had repeated the injection every three or four days. It had been amply demonstrated that tuberculin hypersusceptibility might be produced in cases in which the diagnosis had been made only by the tuberculin test, so that the one marked reaction which the test had developed made the individual, slight as the disease was, for a long time so hypersusceptible to the toxin that it became exceedingly difficult to produce any tolerance when the treatment was begun. 2. The treatment must be continued for several months. Both of his cases (iritis) relapsed after treatment was discontinued after six weeks and two and a half months, respectively. Both patients began improving after treatment was resumed. The one case was under treatment for over six months. The second case was still under treatment. 3. In the treatment very small doses of T. R.. should be given at first. His patients received 1/500 mg., which was gradually increased 1/500 mg. more each time until they received 1/37 mg. Injections were given twice a week. He had followed the suggestions of Dr. Trudeau as to the size and frequency of doses. ("Tuberculin Treatment of Pulmonary Tuberculosis," *American Journal of the Medical Sciences,* June 1907.) 4. A negative reaction, general or local, did not prove that the case was not tuberculosis. His first patient never gave any reaction, and yet was entirely cured of tuberculous iritis with tuberculin injections.

Dr. Arnold Knapp said that he was very much interested in the papers of the evening because the topic was an unusually important one for ophthalmologists. There had been unquestionably a great many cases of ocular tuberculosis which had not been recognized, and he was glad we were making progress in detecting this affection. It seemed to him that a subcutaneous tuberculin test should be applied in every chronic eye case with indefinite clinical symptoms. They had no trouble in getting their patients to enter the hospital for a few days to permit this diagnostic test. The local reaction was, of course, reassuring, but in certain cases of choroiditis it might be absent, though the case was unquestionably tuberculous. He had never seen the local reaction during the diagnostic test cause any retardation in progress toward recovery. On the contrary, there had often been a surprising improvement which sometimes did not persist. He had been able to watch the results of tuberculin treatment in quite a large number of cases. Many of these profited by the painstaking and persevering treatment of Dr. Török at the New York Ophthalmic and Aural Institute. In general the best results were seen in tuberculosis of the conjunctiva, the cornea, and the sclera; while in most affections of the deeper parts of the eye the results were disappointing. It had seemed to him that a great deal could be accomplished in these city patients if we were better able to look after their general health, to keep them in better hygienic condition. Dr. Derby's discription of the tuberculosis class which was conducted in conjunction with the Massachusetts Eye and Ear Hospital had been extremely suggestive. He thought that unquestionably this should be a part of every eye dispensary.

Cancer of the Gastrointestinal Tract.—William J. Mayo concludes an article on the surgical cure of cancer by saying that "it can be shown conclusively that there is no reason why operations for cancer of the gastrointestinal canal should not show results as good, both immediate and remote, as after operations for cancer in any other part of the body."—*St. Paul Medical Journal.*

Pathological Society of Philadelphia.

At a stated meeting, held January 13, Dr. W. T. Longcope presented specimens of dilatation of the abdominal aorta, possibly of syphilitic origin, with fibrinous deposition, and thrombosis of the renal artery on one side. Both kidneys exhibited evidences of chronic inflammation, the more marked on the side of the thrombosis. The patient was a young colored woman who presented a number of other morbid conditions. Dr. Howard T. Karsner presented a specimen of "Congenital Syphilitic Osteochondritis." The gross appearance of the lesion was that of a light band of demarcation at the diaphysoepiphyseal junction, and it could be found in instances in which because of decomposition of the fetus it might be impossible to demonstrate the presence of the treponema. Dr. Homer F. Swift of New York City read by invitation a paper entitled "Serum-diagnosis in Syphilis." He elucidated the principles on which the serum-reaction of syphilis is based, outlined the methods of application, and gave a résumé of the results thus far attained. He pointed out the especial utility of the procedure in the diagnosis of the disease in doubtful cases, or its exclusion when not present, and the desirability of instituting treatment as soon as the diagnosis is made without waiting for the appearances of secondary lesions and persisting in the treatment so long as the reaction is present and intermitting or remitting it as the reaction subsides. The reaction is to be considered one of the symptoms of syphilis, and like other symptoms it cannot be expected to be present invariably in every case. However, of all the symptoms of syphilis it is the most common and the most trustworthy. In discussion Dr. Hideyo Noguchi of New York City pointed out the trustworthiness of the modification of the original Wassermann reaction that he has developed. During his short visit he had examined 59 cases of most varied kinds taken without selection at the Pennsylvania Hospital and not in a single non-syphilitic case had he obtained a positive response. In a case of undoubted syphilis and in several of tabes and paretic dementia positive responses were obtained. In all of these instances the source of the blood was entirely unknown to the examiner. The test has been employed also in New York City by a considerable number of investigators in more than 2000 cases, and it has proved eminently satisfactory. To secure correct results the investigator must have sufficient skill, be thoroughly familiar with the technique and operate only with irreproachable reagents. Dr. Ellen P. Corson-White related that she had performed the Wassermann reaction and the Noguchi modification in more than 500 cases, and the results were in every way convincing. Dr. E. E. Krumbhaar presented a communication entitled "Adams-Stokes Disease: Report of a Case of Complete Heart-block without Lesions of the Bundle of His." The patient had been a man, 65 years old, who for a number of years had presented a bradycardia of the most extreme degree, the heart at times beating not more than three times in a minute, together with attacks of syncope. Tracings of the pulsation of the heart, of the jugular vein, and of the carotid artery showed a total dissociation of the beats of auricles and ventricles. The patient died in one of these attacks, and post-mortem examination disclosed a moderate grade of chronic endocarditis, with thickening of mitral and aortic leaflets, and a considerable degree of generalized myocarditis. Macroscopically there appeared to be no lesion of the bundle of His, and microscopical examination disclosed only a slight degree of fibrosis that could not be considered to be in excess of the normal. There was a slight degree of fibrosis of the bundle of Keith in the right auricle, but Dr. Krumbhaar said that it was impossible to maintain that this almost insignificant anatomical alteration was responsible for the symptoms observed during life.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of February 12, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	639	185
Diphtheria	395	47
Measles	861	14
Scarlet Fever	642	37
Smallpox	—	—
Varicella	178	—
Typhoid Fever	52	8
Whooping Cough	13	6
Cerebrospinal Meningitis	4	5
Malarial Fever	—	—
Totals	2,784	302

Blue Color and Flies.—Marre and Fe state that corn sheds painted blue on the inside are remarkably free from flies. They advise painting all sheds with chlorinated lime containing ultramarine in order to improve the purity of milk.—*Centralblatt für Agrikulturische Chemie.*

Modifications of the Peripheral Sensibility to Pain During Pregnancy; a New Apparatus for the Study of Sensibility.—Giovanni Pandolfi describes a new apparatus constructed by him for the accurate testing of sensibility to touch and pain and its application to testing the pain sense in pregnant women. The apparatus consists of a steel point so attached to an ordinary microscope tube that the sensibility may be estimated in turns of the focusing screw. To do away with the factor of suggestion he covers the eyes of the patient. He tested this method in thirty pregnant and sixteen unpregnant women, with the result that he found sensibility to pain to be much decreased in pregnancy. This accounts for the endurance of the puerperal and pregnant woman of operative procedures of some severity without much complaint. He believes that sensibility to pain is much diminished during the pregnant state.—*Annali di Ostetricia e Ginecologia.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 11, 1910:

		Cases.	Deaths.
CHOLERA.

THE MODERN VIEWS OF HEREDITY, WITH THE STUDY OF A FREQUENTLY INHERITED PSYCHOSIS.*

BY CHARLES L. DANA, M.D., LL.D.,

NEW YORK.

THE text for my present paper, and some justification for calling attention to the subject of Heredity just now, is found in the following rather remarkable announcements:

In a report on the inheritance of vision, and on the relative influence of heredity and environment upon eyesight, recently published by Amy Barrington and Karl Pearson (No. 5 of the "Eugenics Memoirs," University of London) I find the following conclusions: 1, There is no evidence whatever that overcrowded and poverty-stricken homes or physical ill conditions or immoral parentages are markedly detrimental to the children's eyesight; 2, there is no sufficient or definite evidence that school environment has a deleterious effect on the eyesight of children; 3, there is ample evidence that refraction and keenness of vision are inherited characters.

In an article published by Professor Pearson, in the *Biometrika,* Vol. III, 1904, the writer announces, after several years' study of inheritance in groups of individuals, that the mental and moral traits of parents and ancestors, are transmitted in just about the same proportion as are physical traits.

There is a large and important body of investigators who call themselves *biometricians,* and who are studying the problems of heredity by means of measurements and statistical analyses of large groups of individuals. The whole burden of their teaching is to the effect that the important traits of a race are inherited, that the most important thing for the progress of the race, is to improve the stock, and that it is a waste of time, effort and money to try to educate bad stock. Their theories give a blow at once to a large amount of the educational activities now turned in the direction of trying to help the retarded, the backward, and the abnormal.

England, says Profesor Pearson, is suffering from a dearth of intelligent men. It is falling behind America and Germany in its commercial progress and activity. The relief from such a condition is not to be found, he says, in introducing technical schools and improved methods of education, but in persuading the intelligent classes and the good stock of the country to have more children. The increase in the population comes now from an inferior stock. We are told by certain anthropologists that the mixture of different races is beneficial, and that the combination of a mixed stock in an American environment, is going to produce a new and great race. The biometricians would not, I think, admit this view at all. At least not without studies showing that the mixed stocks are good stocks.

The laws of heredity, as discovered by Mendel, and elaborated by his followers, show that you cannot by mixing hybrids, produce a pure stock, that there will always be a majority of hybrids, a minority of pure stock and another minority of bad and abnormal stock. In other words, if, for example, we mingle the Anglo-Saxon with, let us say, the Spaniard, we never get a pure-blended stock, combining the best qualities of either, but we get a hybrid stock, with a minority of individuals showing Anglo-Saxon traits in predominance, and another showing Latin traits predominant. Furthermore, if we bring into our nationality races or stock with distinctly abnormal and anti-social traits, these can never be bred-out of our nationality by inter-racial mixture.

Coming to the subject of the physical and mental diseases, the same laws are supposed to apply. We cannot, by the best possible methods of training and education, make a poor stock with mental abnormalities a good one, and if we mix an abnormal stock with a good one, such mixtures will never entirely breed-out the bad.

It is such pronouncements as these, coming from authoritative sources, and backed up by an enormous mass of statistical work and laboratory studies, that make it seem important for medical men to take a little more interest and inform themselves a little more accurately of what is being done to-day by the students of the problems of heredity. The subject is so large a one, and has become of late years so extraordinarily technical, that I cannot possibly succeed in presenting even an abstract to-night of all that is important in the matter. I propose, however, to touch upon two lines of active inquiry which are being carried out, namely, the biometric studies and the Mendelian studies, and to then bring some practical application of this in my own experience in a single limited group of abnormal mental states. The subject is one which was brought to my attention three or four years ago, and I prepared a semi-popular discourse upon it, which was delivered at the Academy of Medicine, under the auspices of the Psychiatrical Society. This address was heard by few, and has never been published. Since it was written, much has been added to the subject, and what I say to-night is not only a condensation of what I said then, but a modification of much of it.

Heredity, as I understand it, means that mode of biological activity by reason of which one generation transmits its characteristics to another. It is one of the phases of that special activity of protoplasm, which used to be called "vital force." It is a kind of

*Read at the meeting of the Practitioners' Society, January 7, 1910.

memory in the cells. By it parents transmit to the offspring similar organs and functions, so that one species reproduces its kind, and also the traits of the family and individual. Heredity represents and carries along in its activity something of all the previous ancestors. Man has what Galton calls a "nature" or individual character and personality. This is made up of three things: First, and most important, is his heredity or his inherited characters. Second, certain changes or additions, due to accidents of his conception and growth before birth. Third, the acquired traits which result from his education and environment. We cannot express in figures how large a part of man's "nature" belongs to heredity. It is the large and fundamental part, especially as regards general characters and species. It has been generally believed, and is still maintained, that the *mind* of man has a "nature" in which individual action is freer, and that our mental inheritance can, in good measure, be controlled and directed by what is added or acquired. So that, as man evolves and becomes more developed as regards his brain and intellect, he becomes less a slave of his inheritance, and the freedom of our will is, in a sense, measured by the development of this intelligence. The influence of heredity, then, would lessen in the higher types of civilized man. This view, however, which is so hopeful to the moralist and educator, is absolutely denied by Pearson, who asserts that the mental and normal qualities are just as much a matter of stock and ancestry as are the physical qualities.

The subject of heridity is studied by the cytologist from a purely morphological and physiological point of view. This phase of biological science is one which is quite apart from that with which I am concerned now.

For there is another class of investigators who study simply the general facts of heredity, using statistical methods upon large groups of individuals, making measurements, determining which are laid down in the technical language of the mathematician. These investigators are working along two lines: One group call themselves *biometrists* or *biometricians*. They are the followers of Galton, and their work is published in a large, technical journal, and in various special pamphlets.

Still another group of investigators is following the principles discovered by Mendel, and are known as *Mendelians*. I do not mean to say that they are mutually exclusive in their lines of work, for they are not, though there has been a certain antagonism between the methods of the biometrist and of the Mendelian. There seems, however, to be now a coming together of the two.

Now, out of the enormous mass of statistics and observations which have been accumulated regarding heredity, so far, there have been only two principles evolved which can be considered laws. The first of these is "Galton's law of ancestral inheritance," modified by Pearson, and the second is "Mendel's law." Galton's law of ancestral inheritance is simply this: that of all the heritage which an individual possesses, one-half, on the average, comes from his parents, one-quarter from his grand-parents, an eighth from the great grand-parents, and so on. Supposing, for example, that there are two parents, both of whom have a distinctive mental or physical trait. The child, it is found, has somewhat less than half of these traits. How would this be explained? Under the law of Galton, it occurs in this way: the 50 per cent. of traits which he might have inherited from his parents, is offset in a measure, by the absence of these traits in a large part of the ancestry which preceded. On the other hand, if the child had more than the talent of the two parents, it is not that their union intensifies this talent, but that there were also evidences of the same talent in the grandparents and other antecedents. This law explains, in a degree, the inferiority of the children of parents who have been distinguished in certain lines, a fact so often observed.

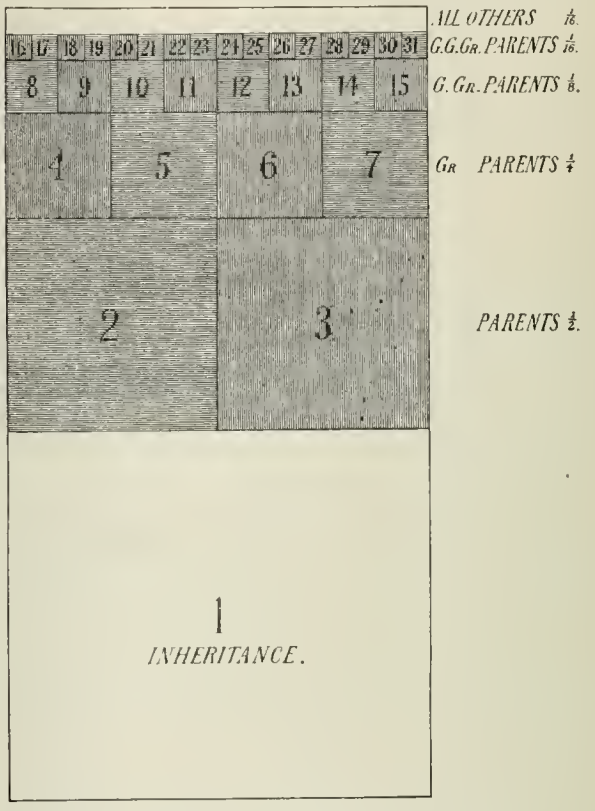

Fig. 1.—Galton's Law of Ancestral Inheritance.

As may be seen, this law of ancestral inheritance helps us in predicting, in a very general way, the nature of prospective generations. It tells us, for example, that a family in which large numbers of certain characteristics exist, will be apt to continue to breed these characteristics. It explains the puzzling fact that the children of geniuses all seem to be rather inferior; and yet, that genius is hereditary. It is hereditary not because the parents have it, but because it is in the ancestral lines, and spreads largely throughout the family tree.

Mendel's law is not a thing that can be stated in any simple formula. It is based, in the first place, on the fact that characters in an individual are transmitted in a unit form, and are not blended with an opposite characteristic, and, secondly, that these unit characters tend to combine in definite proportions, so that, for example, if a tall man and a short woman marry, the characters of tallness and shortness would show in the offspring in a certain definite proportion. Mendel was enabled, for instance, in breeding tall peas with dwarf peas, to predict that at the end of the fourth generation, there would be so many talls and so many shorts, in the proportion of about 1 to 3.

The law, therefore, concerns itself with the phenomena of hybrids, of the breeding together of individuals that have distinctly opposite or pairs of

characters, so to speak. When a pure type of one kind like a tall pea breeds with a pure type of another, for example, like a dwarf pea, it forms a hybrid. Now, when *these hybrids* are bred together, their offspring will not all resemble their parents, but will differ in a certain mathematical ratio. About one-fourth will be like one original pure or tall parent, another fourth will be like the other

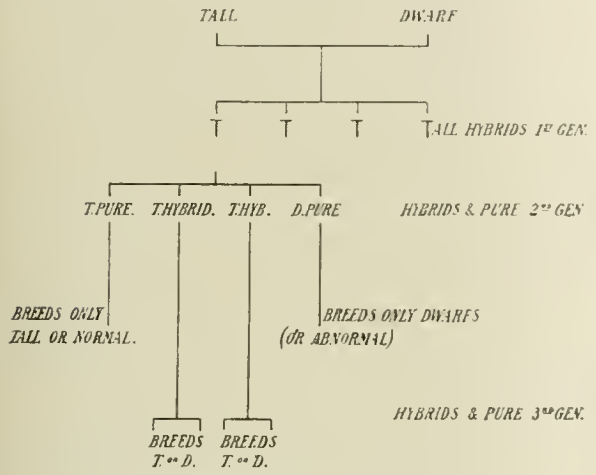

Fig. 2.—Illustration of Mendel's Law.

original pure or short parent, and one-half, or 50 per cent. will be crossed forms. So that the offspring of the breeding will be represented by the formula:

$$B^2 + 2\,BR + R^2$$

Of these, the pure individuals, B and R, will breed true indefinitely among themselves, as to the character in question, while the crosses bred among themselves will again split up into pure and crossed forms, in the same proportion of 1, 2, 1. In other words, the offspring in hybrids will not be hybrids, but half pure and half hybrids.

A second factor of Mendel's law is a distinction between what he calls *dominant* and *recessive* characters. This means practically, that the 50 per cent. of hybrids may appear to be like one of the pure forms because of the two characters of which they are made up, one is dominant to the other, and conceals it. This is shown in the diagram where it is seen that when tall peas are bred with dwarf peas, all the products will be tall because the tall character is dominant, while the dwarf character is recessive.

All this, no doubt, seems very difficult to follow, but, in a way, the dominance and recessive character of special traits are shown all the time in human heredity. We mix the black race with the white, and the black is always dominant. In the marriage of a man who has a mild neurotic taint, with a perfectly healthy woman, the offspring may be healthy because, although it contains still the neurotic taint, such, for example, as the migraine, yet it is recessive to the normal character of the family. On the other hand, a man who has had a distinct development of a serious psychosis, like a recurrent melancholia, marrying a normal woman, would have children in which the dominant trait of melancholia would appear in some of the offspring. The law of Mendel cannot apply strictly to the human race, in most instances, because it is a law which has to deal with individual characters, and human beings are made up of so many characters that the problem becomes too complex, and one character is submerged by the dominance of others. Still, in certain peculiar abnormalities, such as color-blindness, peculiar dystrophies, and other hereditary or family diseases, the Mendelian law has been shown to apply with a fair degree of accuracy. Furthermore, the general principle that hybrids do not breed true, but breed mixtures, pure and recessives, can be applied probably with safety to the intermixtures of families and, perhaps, of races.

Some further remarks may be made regarding the methods of the study of heredity, and the principles which are being utilized. The followers of Galton, the biometricians, base their work upon statistical methods, and deal with large groups of individuals. They have evolved a number of special laws or methods by which certain relationships can be formulated. There is, for example, what is known as "Yule's law" or "formula." This is a formula by which one can determine the relationship between certain conditions, as, for instance, the relationship of deafness to albinoism.

There is also the factor of regression, which is one of the principles connected with the law of ancestral inheritance. In other words, it is the tendency for persons deviating from the average, to return to the same. This is the tendency already referred to which underlies the well-known fact that exceptional men have children who are, as a rule, not so exceptional. The sons of tall parents are a little shorter than their parents, and the sons of short parents are a little taller. It is the ancestral pull, so to speak, the force of the whole inheritance which tends to bring the individual back to the mean. Following out this principal, it has been shown that the extremes of a race, that is, those representing some specially valuable or bad quality, are less productive than the means.

Thus, there are influences at work all the time to diminish the bad effects of heredity on the race, at least, although at the expense of the family. But these influences do not work perfectly if the lives of the parents and the functions of the parents are not regulated in accordance with the rules of ordinary healthful living.

There is a third factor which tends to preserve the sanity and healthfulness of the race, and it consists in the fact that acquired defects and abnormalities are not transmitted to the children. For many years the Lamarckian view was held to a certain extent, at least, viz., that acquired traits could be transmitted. Weissmann propounded a theory that the germ cells which propagate the individual, are independent of the body cells which make up the structure of the system, and any injuries or diseases or defects which were inflicted upon the body cells, do not have any effect upon the heritage of the germ cells which live apart, and propagate only their own defects and virtues. This theory of Weissmann has been very much discussed, but it is now, I think, generally accepted. It is my experience that, in its general lines it represents, so far as human beings go, the truth. We know, for example that if one were to cut off a leg of an individual for an indefinite number of successive generations, there would be no one-legged children born, and so far as mutilation affecting the human race are concerned, it is certainly an established fact that they are not transmitted.

In the same way, it is known that acquired diseases, like syphilis and consumption, are not directly transmitted, or only in very rare instances. We would be able to say the same thing about vicious

habits which have been acquired. A man of naturally good character and life, but who through the influence of bad associations, acquires the alcoholic habit, does not transmit this habit, and in the same way, there are certain "acquired" insanities, such as those following fevers or poisons, etc., the presence of which in an ancestry, so far as it is an insanity, need cause little apprehension on the part of the children. It is true, that if a parent has a disease which is injurious to his general health, which leads to bodily weakness, or by reason of which his tissues have become poisoned and enfeebled, the offspring may be made feebler, and, in this sense, the acquired enfeeblement of a parent may lead to a somewhat enfeebled descendant. But the special character of this trouble, whether it be drunkenness or vice or disease, is not thus passed on. In studying the statistics of insanity, therefore, with reference to its presence in the ancestors, we should take into account the fact that a certain number of these insanities are accidental, and have no direct influence in producing diseases in the offspring.

It has been found in recent studies of heredity, and particularly in the study of the development of monstrosities and freaks of various kinds, and even of idiocy, that serious effects upon the children can be produced by noxious influences that affect the mother during the time that the child is developing; that mechanical influences, like shocks, or chemical influences like poisons and infections, which get into the system at the time of pregnancy, may injure the vitality of the growing germ cells, and produce anomalies and monstrosities. By shaking and disturbing the contents of the fecundated egg in the chicken, all kinds of monstrous pullets can be brought forth.

In my own experience, in the study of the backward children or the idiot class, in which the idiocy was apparently begun at birth, it has been rare to find anything in the ancestors which would explain it, and among the idiot class that come to a private physician's office, I should say that the determining influence, in most cases, could be traced to something which occurred when the child was in the embryonic state. This is not altogether the case in the great mass of idiots found in institutions.

Thus, you see Nature provides these three measures to lessen the injury that would come from the development of disease and bad habits in adult life; these three influences being (1) the tendency to sterility and extinction of degenerate families, (2) the tendency to bring the family back from the abnormal to the normal or average, through the agency of the ancestral "pull," and (3) the refusal, on the part of Nature, to transit what has been acquired.

Leaving the general question, I will take up now one practical side of the matter, *viz.*, that of bad heredity in form of a particular unit character of, *viz.*, that of insanity. How extensive and various does this bad characteristic affect society, and to how large an extent must a family be impregnated with it in order to make it unsafe for the children to marry. As to the extent about one person in every 300 is insane. In a community of 3000 people, there are therefore about 10 insane, and 6 of these have mainly a hereditary type of disorder. As to the seriousness to succeeding generations of the presence of a psychosis in a family we are confronted with many problems: "An uncle was insane or a cousin, or a father or grandfather was insane. Will it therefore be safe for me to marry?" Now, in order to answer this and similar questions, there are four factors in the matter of heredity which we have to consider: (1) Mental diseases are sometimes transmitted directly, that is to say, the father transmits the disease directly to the son, and the son to the grandson. This is known as "direct heredity." This is the most serious form of heredity influence. (2) Another form of heredity is known as "collateral," that is to say, the uncle, or aunt, or cousin or great aunt are known to have had mental disorders. This is a not uncommon thing to find in investigating the history of any family, but it is of vastly less and often of no importance. (3) Thirdly, how many persons are there who had the mental disorder, or *psychosis*, in the family, for this indicates the intensity of the characteristic? (4) What was the nature of the mental disorder for, as I have already said, one-third of the mental disorders are acquired, and those which are "acquired" need not be much feared, while of those which are not acquired, some are more serious in their transmissive power than others. There are, of course, no general rules to be followed inflexibly in these cases, but I think we would be fairly well agreed upon these points: *First*, direct heredity is the most serious and often the only factor to be considered seriously. When a father or mother has had a distinct psychosis, that was not acquired, and which came on early in life, this person takes the very greatest risk in marrying. Direct heredity is of importance in the case of grandparents only in rare cases. *Second*, if the heredity is not direct but collateral only, that is to say, if it involves only an uncle or aunt or cousins, and exists upon only one side, the danger of any transmission is remote, and does not of itself justify a refusal to the marriage. *Third*, if there is no direct heredity, but there is a mental disease in the collaterals on both sides, the danger of marriage is still only moderately great. *Fourth*, when there is an abnormal character in a family, but certain members have bred true for three generations, it will not reappear in that line. The degenerative psychoses and neuroses seem to be mainly or fundamentally due to teratological defects and to rank with such things as color-blindness, polydactylism, etc. But they are of varying degree of dominance. In all probability, the early dementias form the most serious of the degenerative psychoses. It is families, with this brand of psychosis, which should avoid perpetuating themselves. On the other hand "melancholia," or "mania," is less serious in its characters. And, as I have already stated, the late insanities and the acquired, are least serious.

I wish in conclusion to give the results of a special study of heredity in cases having one unit character, viz, that of a functional psychosis, known as *melancholia*, or *manic depressive insanity*. This is a malady which is usually constitutional, is very chronic and very difficult to eradicate from the individual, but which does not lead to any mental deterioration. It has the qualities of a migraine affecting the psychic instead of the sensory sphere. It has all grades of severity, and in its mildest form, it is represented by what is often called *neurasthenia*. Practically all the primary neurasthenias are forms of a functional melancholia, of the abortive type.* Many

*There is, to be sure, a "physiological" neurasthenia, due to persistent strain, infections and overwork, but it is relatively rare. And there are also local neurasthenias due to overwork of an organ.

of the hypochondriacal conditions of early life are simply abortive types of the melancholia which occurs at involution, and most of the depressive neuroses of adult life are simply partially developed attacks of the "melancholia-mania" psychosis.

In studying the heredity of insanity, it has often been customary to study insanity as a whole, and also to study the psychoses of various kinds in the collaterals and the remote ancestors. In my experience, it is only the direct parental heredity which is of much importance to the offspring in the psychosis under question. I have therefore gone over the histories of 111 selected cases in which I was able to obtain a good history of the parents, grandparents, and usually of the collaterals. The cases were all patients in the better walks of life, of whom the family history was well known. The result shows that in this psychosis, in about one-third there is a direct parental heredity, more often found on the father's side than on the mother's. In one set of 51 cases the results were as follows:

	Males.	Females.
Recurrent melancholia	18	33
Direct parental heridity of one parent..	14	
Indirect heredity alone.....	6	
Inheritance of similar psychosis in....	9	

In a second set of 60 cases the percentage of direct heredity was only 25. These cases were well developed types of the psychosis though rarely all custodial cases. In simple neurasthenic depressions this bad heredity is not over 8 per cent. and is rather insignificant.

Among 1246 cases of insanity of all kinds received in Bellevue Hospital, there was a history of direct heredity in 35 per cent.*; collateral heredity in 32 per cent. The direct heredity factor in melancholia among the well-to-do is therefore considerably less than that for insanity in general as it exists among the poor. From which one might infer that there are more influences leading to this psychosis in the exigencies of active life among the better classes; that insanities are more a matter of poor stock among the poor, or of poor environment and stress among the rich.

I have spoken of the melancholia psychosis as a unit-character. But it is not a stable unit like a sixth finger or a color-blindness preserving the same character in different generations. It is rather a variable unit taking different forms but always indicating a psychic defect in the family. It may show itself as an alcoholism or hysteria in the parent and a dementia precox in a child. The major and non-acquired psychoses have all a certain kinship and the different types interchange in the family tree. The melancholia indicates a medium grade of psychic instability and the ancestral "pull" tends to breed it out. But it is a very definite index of defect. It is, I think, a recessive character, as a rule, for I find these patients, if mated well, have sound children, but it seems especially important that such patients mate with a strong stock.

Summary.—1. If we accept the teachings of the advanced investigations into problems of heredity, we must conclude that the efforts in the direction of improving and educating poor stock, including the retarded minds, the abnormal, and the defectives generally, are of little permanent value to society, and do not directly affect racial progress. The work spent on the education of defectives should not make us lose sight of the fact that, to secure real advance we must work for and work with good stock.

2. If, as it seems likely, Mendel's law can be applied to human culture, we must conclude that the mixture of races having distinctly different characters produces a hybrid stock which never altogether breeds pure. Theoretically, about one-quarter would be pure, one-quarter bad or impure, and half would be mixed. The mixed races, therefore, which have opposite unit characters, will not produce a new, pure type, unless we are able to segregate at once the impure and hybrid three-quarters, which results from such mixtures. This may have a bearing on our immigration problems.

3. The law of Mendel affords one helpful indication for, according to it, by the third generation we can definitely say that in certain strains the breed is pure. That is to say, if in a family in which there is a so-called "family-neurosis" or psychosis, youth can look back three generations and find a clean record in his direct descendants, he can ignore his uncles, his cousins, and his aunts.

4. The law of ancestral inheritance (Galton-Pearson) shows that there is always an ancestral "pull" or tendency to bring the individual towards the average. This law, which is called the "law of regression," explains why tall parents have shorter children and short parents have taller children; also why parents of exceptional characters have children that are less so. It also tells us that the qualities of the parents are about equal in hereditary force, to those of all the other ancestry, and that those of parents and grandparents together, furnish three-quarters of the ancestral values. The most important single point, thus, in good ancestry, is the quality of the direct and immediate ascendant.

5. It is quite generally accepted that diseases, malformations, abnormal characters, and morbid habits which are acquired are not transmitted by inheritance. Thus, a person who has distinctly acquired an epilepsy, a migraine, or a psychosis, does not transmit it.

6. The modern studies of heredity show that there are certain characters in a family which are *dominant* and others which are *recessive*. In other words, that certain kinds of abnormalities and deformities or diseases have a tendency to transmit themselves very strongly, and to overpower the more normal qualities, while there are other characters which are recessive or of minor force, and have a tendency to disappear or, at least, to be submerged by the better qualities.

7. The functional psychosis known as manic-depressive insanity shows itself oftenest as a "recurrent depression." This psychosis is directly transmissable and is of direct ancestral origin in nearly one-third of the cases. Its presence in a family should lead to great caution in the marriage of the descendants.

I should not like to conclude this paper without expressing my belief that while hereditary fine stock is of the greatest importance, it is also, I believe, more true than the biometricians would admit, that the human mind is capable of overcoming obstacles and dominating its handicaps, and I should be sorry if the enthusiasm over Eugenics should lessen our faith in the power of the will to determine a man's course, for it is certainly true that the man or

*The statistics were kindly furnished by Dr. M. S. Gregory, physician to the Psychopathic Ward.

woman who is of powerful mould, and is captain of his soul, can greatly alter his ancestral "pull."

TRAUMATIC AFFECTIONS OF THE KNEE JOINT.*

By ROLAND HAZEN, M.D.,

CONSULTING SURGEON, CENTRAL ISLIP STATE HOSPITAL.

BRENTWOOD, L. I.

It is a commonly acknowledged fact that the knee is more frequently disabled by injury involving the internal joint structures than any other joint of the human anatomy. Every physician, much to his chagrin, encounters "chronic knees," following injuries, direct or indirect, and often slight, in which the disturbance of function, through fluid formation, pain, locking, grating, weakness, or limitation of motion, is either unduly prolonged or appears in recurrent attacks. While it is impossible, with our present knowledge of these conditions, to determine just which structure is at fault in every individual case, there has appeared within recent years sufficient operative and post-mortem evidence to demonstrate that in practically all of these cases there is some derangement of one or more of the several complicated structures found within the capsule of the joint, of sufficient severity to mechanically prevent a return of the normal function and often, if not removed by operation, to seriously endanger the integrity of the joint.

It is a striking observation that this tendency for trauma to be followed by prolonged or recurrent disability is peculiar to the knee joint, and that in this joint it is common. And furthermore, so far as I have been able to ascertain, man stands curiously alone in the animal kingdom in his tendency to internal derangements of this joint. Veterinary text-books give scant attention to affections of this joint beyond a description of outward dislocation of the patella.

These observations indicate that there is some fundamental weakness in the construction of this joint, as compared with other joints of the body, and also as compared with the corresponding joint in the lower animals; a distinction which has not been appropriately emphasized, nor am I aware of its having been demonstrated by comprehensive anatomical comparisons. In venturing upon the anatomy, I do so with the belief that it may contribute to our knowledge of the causation of these affections peculiar to the human knee, and thereby aid in placing their diagnosis and treatment upon a more rational basis.

In the quadrupeds as a class, we find that this joint presents two main features of fundamental difference from that in man.

1. On account of the horizontal position of the quadrupeds, the condyles of the femur are decidedly elongated, and project directly posteriorly at right angles from the end of the bone. The articular surfaces are mounted on the ends of the condyles, and are separated from each other by a distinct interval. The elongated trochlear surface, for the articulation with the patella, is situated well up toward the anterior surface of the femur. Thus, these three articulations are well separated from each other and, therefore, are comparatively independent of each other in their actions. In fact, in some of the lower animals, they are separated by a distinct synovial cavity for each of these articulations, while in others there is but a partial confluence of these cavities. The space between the ligamentum patellæ and the articular surfaces is occupied by a soft, fatty, pad, presenting its posterior aspect to the interior of the joint, as a smooth, flattened surface. This arrangement affords a comparatively simple mechanism, with apparently little opportunity for mechanical interference with the joint activities. (Fig. 4.)

The erect position in man, however, brings the condyles almost into the axis of the femur. The articular surfaces are broadened for weight bearing, enlarged for the increased range of motion, and are less widely separated from each other. The trochlear surface connects directly with the condylar articulations, and the joint is converted into a compound, confluent structure, with but a single synovial cavity. The fatty tissue within the capsule anteriorly has consequently changed to a broadened and horizontally flattened wedge, pointing posteriorly, and now it presents as a menacing adaptation, extending its edges, flaccid and frayed, into the very cogs of this complicated machine. Little wonder if these edges, brushing the articular surfaces with every movement, were not occasionally caught between the bones, especially when congested by trauma, or in consequence of a wrench of the knee. (Fig. 1.)

FIG. 1.—Outer aspect, left human knee joint, showing the two external lateral ligaments, relaxed in flexion, and the fatty collection beneath the patella; the horizontally flattened wedge shape of the latter is apparent though somewhat obscured by the prominence of the alar ligament in the foreground extending up to the side of the patella; the posterior edge of the fatty wedge, irregularly fringed, is indistinctly seen within the joint lying on the upper surface of the semilunar cartilage, and the ligamentum mucosa is shown passing upward to attach in the intercondyloid notch. Note the relation of the subpatellar bursa to the fatty pad, the position and relations of the popliteus tendon, the continuity of the articular surfaces of the femur, and the extent of the synovial membrane with its fatty collection above the patellar articulation and its occasional fringed projections.

2. In both the mammalian and the human knees there are two main groups of muscular supports in

*Read before the Associated Physicians of Long Island, October 23, 1909.

relation to the joint. The quadriceps extensor, anteriorly, and the ham-strings posteriorly. These effectually control flexion and extension. In the quadrupeds, however, we encounter an additional group of lateral controllable supporters, variously found in the different species. This group is made

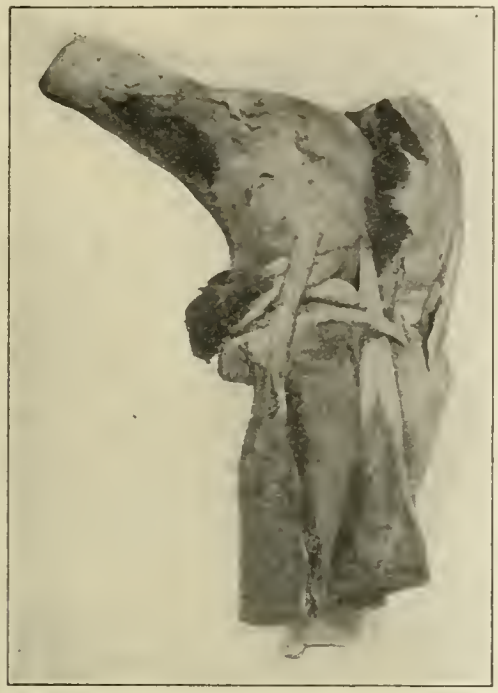

Fig. 2.—Outer aspect, right sheep's knee (stifle joint), showing and ligamentum patellæ and an external accessory ligamentum patellæ, the tendon of the extensor communis digitorum arising from the anteroexternal aspect of the condyle; the external lateral ligament and the perineus brevis arising in common from the lateral aspect of the condyle; and the position of the tendon of the popliteus muscle.

up of ligamentous and tendinous structures. The ligamentous consist, chiefly, of two accessory ligamenta patellæ of large size, one on each side of the patella. They pass somewhat obliquely across their respective condyles to be inserted into the corresponding lateral aspects of the tibia. These are well represented in the horse and the cow.

There are three of the tendinous lateral supports that are commonly found; two external and one internal. They consist of: the perineus brevis, taking its origin from the external condyle of the femur, in conjunction with the external tibiofemoral ligament, and lying on the lateral aspect of the joint; the extensor longus digitorium, taking its origin from the external condyle, in a stout tendon, which passes freely over the anterolateral aspect; and the semimembranosus, occupying a lateral position along the inner side of the joint, its tendon passing beneath or in conjunction with the internal tibiofemoral ligament, to insert into the tibia. Sutton[1] gives evidence to show that the internal lateral ligament is derived from the adductor magnus muscle. The relation of the insertion of the latter to the upper attachment of the lateral ligament suggests that the continuity of these structures, in times past, has also served as a lateral controllable support. By means of these attchments the joint tension, lateral motion, and rotation, are under muscular control in all degrees of flexion and extension. (Figs. 2 and 4.)

In man, however, these controllable lateral supporters are entirely wanting. The popliteus affords the sole lateral tendon in man and is identical with that in the lower animals. Its control over joint tension and lateral motion, however, is very slight, it being essentially an internal rotator. There is but the single ligamentum patellæ, and in the place of the above lateral tendons there are found, respectively, the two external and the internal lateral ligaments. These comparatively delicate bands become tense on extension and relaxed on flexion, thus exerting no controllable fixity over the joint during activity. And thus it appears that the human knee joint is comparatively ill provided, anatomically, to resist the strains and twists to which it is subjected through the various trades and sports to which man lends himself. (Figs. 1 and 3.)

A dissection of the sheep's knee (stifle joint) (Figs. 2 and 4) shows many of the above features. There one accessory ligamentum patellæ, about one-third of the size of, and lying about one-half inch external to, the ligamentum patellæ. The small external lateral ligament is blended with the origin of the perineus brevis, and the anteroexternal ligament is of large size and is purely the tendinous origin of the blended tibialis anticus and the extensor longus digitorum. The latter tendon arises from the anterior portion of the external condyle, and lies within the capsule and about one-third of an inch external to and parallel with the ligamentum patellæ. The semimembranosus tendon passes along the inner aspect of the joint and beneath the internal lateral ligament to insert in the lateral aspest of the tibia. The external semilunar cartilage is attached posteriorly on a different plan from that in man. Instead of being inserted into the tibia anterior to the posterior crucial ligament, it passes upward and inward obliquely over the posterior articular surface of the external condyle to be inserted upon the internal condyle just above and

Fig. 3.—Inner aspect, left human knee joint, showing the internal lateral ligament; the posterior position of the semimembranosus muscle and tendon; and the suggestive relation of the insertion of the adductor magnus to the upper attachment of the lateral ligament.

external to its articular surface. Now, in movements of the joint, the external condyle, being almost spherical in shape, rolls back and forth with practically no sliding motion, and the posterior portion of the external semilunar cartilage is seen to wind up on the condyle during extension and to

unwind during flexion. This posterior guy, together with the external lateral and the anteroexternal tendinous supports thus lends a firm and controllable fixity of the external condyle in all positions of the joint. The internal condyle is bean-shaped and fits into the deep concavity of a very thick semilunar cartilage. Its motion is almost entirely that of a gliding on the semilunar cartilage, with but slight anteroposterior shifting of the geometrical center. This difference in the motion of the two condyles is perceptible, to a slight extent, in the human knee. The trochlear surface of the femur is entirely separate from the articular surfaces of the condyles, instead of being blended with them as in man. This is due to the greater length of the condyles, and their axes being carried posteriorly to a right angle with the shaft of the bone. The synovial cavity is divided into two portions, the one for the external condyle which does not communicate with the larger one for the internal condyle and patella.

Fig. 4.—Inner aspect, right sheep's knee (stifle joint), showing the internal lateral ligament; the lateral position of the semi-membranosus muscle and tendon; and the fatty collection beneath the patella; note the posterior surface of the latter—smooth, vertically placed, and with no projecting edges; also note the elongation of the condyle and the distinct separation of its articular surface from that of the trochlear surface for the patellar articulation.

In recalling the anatomy of the human knee, as it bears upon our present consideration, we find here a large joint, occupying an exposed position, subject to the forces of powerful muscular action and weight bearing, and dependent entirely for its strength upon its ligamentous and muscular attachments. It differs more especially from other joints of the body, in the relatively large collections of fat found within its capsule, and, from other hinge joints, in its lack of the usual bony restrictions to rotation and lateral motion. These factors naturally invite the occurrence of trauma from direct and indirect causes.

The patella is practically its only protection, anteriorly, against direct injury. That direct injury is so commonly followed by acute synovitis in this joint, we have to look to the arrangement of the synovial membrane, for the chief explanation. Here we have the largest joint cavity in the body, lined by a delicate synovial membrane, which is exceedingly rich in blood supply, thus lending itself readily to congestion and excessive secretion. Its surface is increased by its following the irregularities of the fatty pads within the capsule, from the edges of which it projects as synovial fringes. As this membrane extends both above and below the patella, and laterally over the condyles, its exposure to direct injury is evident.

There are three collections of fatty tissue, covered with synovial membrane, found within the capsule of this joint. One is found between the ligamentum patellæ, femur, and tibia, and is a somewhat flattened, triangular, wedge-shaped pad, horizontally placed, with its base anteriorly, and an angle extending to either side. The apex extends up towards, and less frequently attaching into, the intercondyloid notch; this apex and the lateral fringes constituting the ligamentum mucosa. A second collection extends from the lateral angles of this fatty pad, upward on either side of the ligamentum patellæ, to the lateral and inferior aspect of the patella. Its free margins constitute the ligamenta alariæ. The third collection is of lesser extent and is found in the suprapatellar region. The free edges of the mucous and alar ligaments are made up of delicate fringes of synovial membrane, which, on account of their positions are likely to be caught between the adjacent articular surfaces. (Figure 1.)

Indirect injuries are even more potent than direct, in the causation of disturbances in the knee joint, and are certainly more commonly followed by chronic or recurrent trouble. As the lateral and crucial ligaments become relaxed on flexion, it is in this position that twists and lateral strains are prone to occur, resulting in injury to the internal joint structures. If either one of the lateral ligaments becomes stretched or ruptured through strained positions, injury, or disease, the corresponding side of the joint is thus predisposed to injury of its semilunar cartilage, synovial fringes, or fatty tissue.

The greater frequency of derangements at the inner side, as compared with the outer side, of the joint is the result of evident anatomical causes. In 428 cases of recurrent effusion with definite signs of derangement within the joint, recorded by Bennett,[2] the inner side was affected about three times as often as the outer. Now in external rotation of the tibia, we find that motion occurs chiefly between the internal condyle and the tibia, motion at the outer side of the joint being checked by the external lateral ligaments, and vice versa for internal rotation. But the crucial ligaments are so arranged that internal rotation is limited by their crossing, whereas in external rotation they are uncrossed. Therefore, external rotation, and consequently motion at the internal condyle, possesses a freedom not obtained at the outer condyle. Thus we find the inner side more frequently damaged than the outer, and, conversely, external twists are more commonly productive of trouble than internal twists. There is also a certain degree of control over the outer side of the joint which does not exist at the inner, because of the origin of the popliteus muscle from the external condyle, and its grooving, and consequent splinting, of the external semilunar cartilage.

The internal structures are thus seen to be in such relation to the joint activities as to cause more or less interference with its function, when lacerated, displaced, congested, and hypertrophied, or

otherwise altered as the result of injuries, twists, ill-directed muscular action, or undue ligamentous relaxation. There are abundant instances in literature, in which operation has shown these various conditions to be the seat of the trouble, in knees that have failed to respond satisfactorily to, or have recurred after, the most diligent and conscientious treatment.

Many of these conditions can be definitely diagnosed beforehand, though there is still much to be learned about the differential diagnosis of the structures involved, and the character of the change undergone. This knowledge is to be gained through increased familiarity with the component structures of the joint, in regard to their functions, and their relations to each other during joint activity; greater care in the study of the action of the causative forces, and of the subsequent history of the cases; and closer attention to the physical examination of the normal as well as the injured knee.

In a routine examination of an injured knee, both knees should be exposed and corresponding points compared. The presence of fluid is detected by means of the ordinary tests. The tension of the ligaments should be investigated, both in the extended and flexed positions, and it is essential that there be complete muscular relaxation during the examination. To secure this relaxation the patient is best placed flat on his back for extension, and seated on a table with the feet dangling for flexion. The range of rotation, anteroposterior, and lateral motion are then determined. There is considerable variation upon these manipulations in knees that are otherwise normal, though the finding of undue laxity in the deranged knee may be of fundamental importance. Attention should be directed to the prominence of the fatty pad, as determined by the state of the normal depressions to either side of the ligamentum patellæ. The joint should be carefully palpated for areas of thickening of the capsule, synovial membrane, or fat content, nodules, foreign bodies, abnormal semilunar cartilages, etc., and for the effects of motion upon these conditions when found.

For this examination I have found it most convenient and satisfactory, to have the patient lying comfortably upon his back with the knees relaxed. The leg is grasped between the two hands just below the joint, and gentle, passive flexion, and extension are made, though not sufficiently to drag the heel back and forth, as this brings on muscular contraction. The two thumbs are free to palpate the joint systematically, during this manipulation, and very slight changes are thus often easily outlined, which otherwise are not detectable. This manipulation is to be repeated with the knee placed in different degrees of flexion. Grating on manipulation, limitation of motion, and tenderness on pressure should, of course, be taken note of.

A summary of forty consecutive cases of traumatic knee affections, personally studied, brings forth some features of practical interest.

In all but three of these cases, the disability was referable to the internal joint structures, and, in these three it was referred to the tendon of the popliteus, or its bursa. Note the contrast with that of trauma of other joints, in which a simple contusion, sprain, or dislocation are the common results. Recurrent disability, often without apparent cause, was common. Fifteen, or more than one-third of the cases, either came for the treatment of a recurrence, or had a recurrence while still under observation.

Direct injury was not as common a cause as indirect. In fifteen cases, the injury was direct; in nineteen, due to twists; and in four, the condition resulted from unnatural or strained positions. Those due to direct injury, mostly ran the usual course of acute synovitis, and were cured in two to four weeks. One had recurrent trouble, with thickening, of the synovial fringes, in the anterior portion of the joint, and two had continued trouble, evidently from injury of the semilunar cartilages. In the cases due to twists, thirteen were heard from subsequently, nine of which had recurrences or continuation of the trouble. Those spoken of as due to unnatural or strained positions, were all patients whose occupation required their assuming a stooping, or kneeling position, the greater part of the time, and there was no other accountable cause. In all of them the fatty pad was prominent and thickened, and bulged at the sides of the ligamentum patellæ. Fluid was present in only one of these cases, and three of the four are known to have had recurrences of the disability, which consisted of pain, chiefly on extension, and weakness.

In twenty-four cases, the onset was sudden, and in five it was gradual. The latter included three of the above cases, and two others, in which thickened synovial fringes was the evident cause. Pain was recorded in twenty-five cases, grating on manipulation in eleven, weakness of the joint in eighteen, in many of which this weakness was the chief symptom, and locking of the joint in five. A number of cases were unaccompanied by effusion into the joint, three of which were evidently cases of hypertrophied synovial fringes.

In the differential diagnosis of conditions within the knee joint, producing chronic or recurrent disability, dislocated semilunar cartilages, and foreign bodies are better known and more frequently described, though often erroneously diagnosed for the more common condition of hypertrophy of the synovial structures.

The semilunar cartilages may be displaced, lacerated, fractured, or frayed at their edges. The characteristic feature of these injuries is the locking of the joint, which, however, is not necessarily present. The injury is usually a twist, when the leg is flexed near a right angle, the onset is sudden, the locking is complete until relieved by manipulation, and recurrence of the locking is the rule. The internal cartilage is by far the more frequently affected, and the detachment most commonly occurs at its anterior extremity. The injured cartilage may or may not be discovered by palpation. Undue mobility may be detected, or a hard nodular mass may be felt, which usually disappears on extension, and becomes prominent on flexion. In half of the cases in which the external semilunar cartilage is involved, the symptoms are referred posteriorly to the popliteal space. Relaxation, or rupture of the internal lateral ligament, if present, would contribute to the evidence.

Given a firm nodule, laterally placed at the articular junction, we may state, as a rule of probability; that, if found at the inner side it is a dislocated semilunar cartilage; whereas if at the outer side, it is not cartilage, but rather a bursitis or synovitis of the tendon of the popliteus muscle. The latter condition usually results from twists, and produces chronic disability through weakness of the

joint, and pain on flexion, or rotation. The nodule presents just anterior to the long external lateral ligament, where the tendon grooves the external semilunar cartilage, and is more prominent in semi-flexion than in any other position. (Fig. 1.) In consistency it is of cartilaginous density when small. The diagnosis ultimately rests upon the fluctuation, which is difficult of detection, except when of large size.

Free bodies may be soft, when derived from hypertrophied villi, which have become nodular and attached by but a thin pedicle. These usually result from trauma, but commonly occur in tuberculous synovitis, in which case the evidences of the tuberculous nature are otherwise present and clear the diagnosis. Hard bodies are often associated with rheumatoid conditions, in which case the diagnosis is based on the constitutional condition, and the involvement of other joints. The occurrence of multiple cartilaginous free bodies is occasionally encountered, and these cases are probably examples of displacement of cartilage cells, in the synovial membrane, which is derived from the same mesoblastic tissue that forms the articular ends of the bones. Trauma, causing the chipping off of a portion of the articular cartilage, is undoubtedly an important cause of the production of free, hard bodies. Barth[3], in experiments on animals, chiselled off pieces from the bones and found that they attached themselves to the capsule, after which the bony portions absorbed and the hyaline cartilage remained; they also became covered with an envelope of connective tissue. The histology of these bodies is identical with that of the cartilaginous bodies removed from the human knees. Virchow stated that loose bodies can and do grow after becoming loose in the joint, being nourished by the synovial fluid. Free bodies tend to shift their position within the joint, and when they present to view or palpation, they are not difficult to diagnose. They may cause locking, when placed near the line of articulation, but the locking is not so fixed as in dislocation of the semilunar cartilage, and they frequently slip out again on slight motion without resorting to manipulation. Often they are located in the upper part of the synovial cavity, where they are more readily recognized.

The crucial ligaments, both anterior and posterior, may be ruptured. Pagenstecher[4] reports three cases in which he united, by suture, ruptured crucial ligaments. Theoretically we should expect this injury to permit of undue anterior, or posterior, displacement of the flexed tibia, depending upon whether the posterior or the anterior ligament is involved.

Undoubtedly the most common cause of chronic and recurrent disability of the knee is to be found in the production of hypertrophied villous formations of the synovial membrane, following trauma. Since these affections of the synovial membrane have passed into the hands of the operating surgeon, their rôle in this connection has become better known. In 1903 Painter and Erving[5] gave a complete account of thirty-three operations for chronic villous arthritis, in which hypertrophied synovial villi were removed from the joints, with excellent postoperative results, and many similar reports have appeared in literature. The villi vary in number from a few, of considerable size, to a dense studding of the membrane with many small papillary growth. The formation of these enlargements is primarily due to congestive thickening, which, on subsiding, is followed by the production of a fibrous overgrowth, beneath the synovial membrane. This fibrous tissue has, apparently, a peculiar tendency to overproduction, as a result of the stimulus of congestion. A striking characteristic, in these cases, is that the hypertrophy does not appear until some interval of time has elapsed after the trauma, though the knee has not felt entirely normal during this interval. The fluid may have nearly, or entirely, disappeared, and it usually returns with the return of the symptoms, which consist of pain, grating, weakness, and limitation of motion. The trauma may result from direct external injury, or from internal injury from irregularities of the surfaces of the bones, foreign bodies, etc., acting directly in setting up the primary congestion.

When the synovial membrane, covering the fatty pads, or their marginal fringes, is injured, the result is a congestion which, if not quickly subdued, leads to a similar fibrous hypertrophy. The fibrous tissue is here interspersed with the subsynovial fat, forming more or less pedunculated masses, of fibrous or lipomatous consistency, depending upon the preponderance of the fibrous or the fatty element. The extent, number, and consistency of these enlargements vary in different cases. There may be a single nodule, a diffuse bulging enlargement of the fatty pad, or a marginal row of more or less pedunculated tabs projecting from the ligamenta mucosa or alariæ.

In disability of the knee following a misstep, a wrench, or a twist, our first thought should be of injury to the fatty tissue, or its synovial fringes, they having become engaged and pinched between the articular surfaces, the result of undue rotation or lateral bending of the joint. Relaxation of the lateral or capsular ligaments, from whatever cause, naturally renders the joint more susceptible to this occurrence. There may be a condition of lack of sufficient moisture in some joints, which causes the fringes to become primarily caught and pinched between the bones. General thickening of the fatty pad, from pressure from without, or possibly, from pressure of the capsule through muscular action, in the cases whose occupation requires constant stooping and kneeling, naturally causes the fringes to be crowded into the joint, and eventually to become hypertrophied. The hypertrophied tabs are here produced gradually, and without any direct sudden injury. An enlarged subpatellar bursa also presses the fatty pad into the joint, and produces the same internal condition. Its detection is to be found in the fluctuation at the sides of the ligamentum patellæ near its insertion. The masses thus formed continue to act as foreign bodies and produce recurrences or exascerbations of the symptoms, which consist of weakness and pain, usually with effusion, and often limitation of motion and catching of the joint.

These swellings can be felt as nodular or cord-like thickenings within the joint, usually at, or just above, the line of articulation, on either side of the ligamentum patellæ, though more commonly to the inner side. They are most easily palpated upon extension of the knee, and usually disappear on flexion. A single nodule when caught in the joint becomes quite firm and may be mistaken for an injured or displaced cartilage. But in this case the locking will not be so acute and absolute, and the nodule will be found to change in consistency, being softer on flexion and firmer on extension. It also becomes

more prominent on extension, whereas the displaced cartilage does not alter in consistency, and usually becomes more prominent on flexion.

It may be possible to distinguish the hypertrophied synovial tabs arising from the ligamentum mucosa from those arising from the ligamentum alaria by the position of the nodules, and, furthermore, by the fact that the former are more likely to become pinched between the femur and the tibia, on extension, and consequently to produce pain and weakness on going upstairs, whereas the latter are more likely to become engaged between the patella and femur, on flexion, and therefore causing difficulty on going downstairs.

The alar and mucous ligaments may also be detached, or lacerated by injury, when the edges are found, at operation, to be turned over or jagged. There is nothing in the history of these cases beyond the very sudden onset, to distinguish them from the above. The fatty collection in the suprapatellar region is less commonly involved..

As a further aid in the diagnosis of knee conditions, *x*-ray examinations of the joint, after a distention of the synovial cavity with oxygen, are advocated by Wollenberg[6] and Hoff,[7] who claim that a very clear picture is thus obtained, showing dislocated cartilages, floating bodies, rheumatoid and other forms of arthritis, proliferation of synovial fringes, and tubercular disease of the bones and synovial membrane.

It is not the purpose of this paper to consider the treatment. The operative aspect, however, deserves brief notice. It is seen that the structures commonly at fault are such as permit of operative removal or repair without endangering the functions of the joint; their presence, acting as foreign bodies in the joint, tends through repeated traumatic congestion to perpetuate and augment the disability; and they are usually located anteriorally and readily accessible to operative relief. When the cause of the disability is diagnosed beforehand the question of operation rests upon the merits of the case. In obscure cases exploratory incisions should be performed, but not until one is satisfied that the disability is persistent in the absence of adventitious thickening.

In conclusion I desire to recall that:

Anatomically the human knee-joint is peculiarly predisposed to injury to its internal mechanism.

Clinically traumatic knee conditions resisting conscientious treatment for months or followed by recurrent attacks of disability are almost invariably caused by some derangement within the joint.

Twists are far more likely to produce prolonged or recurrent disability than direct injuries.

The degree of damage to the joint structures is not dependent upon the severity of the trauma.

The synovial structures are most commonly the seat of the disability.

The structures at fault are usually palpable and should be more commonly diagnosed.

These injured structures are usually amenable to operative relief. Exploratory incision is a proper procedure in obscure cases.

BRENTWOOD, L. I.

THE WASSERMANN REACTION.*

ITS CLINICAL VALUE.

BY DAVID EDWARD HOAG, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL; ASSISTANT ATTENDING PHYSICIAN, DEPARTMENT OF NEUROLOGY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

It is now nearly twenty years since pathologists began to realize the value of the blood serum as an aid to diagnosis. In 1895 H. E. Durham and his assistant Greenbaum, while working in Gruber's laboratory in Vienna, discovered that immune serum could agglutinate bacteria. Positive results were obtained in several cases. A few months before Greenbaum had published his results, Widal, in Paris, applied the test, and wrote a succession of papers describing the technique and was proclaimed the discoverer of the reaction bearing his name, he being the first actually to apply the reaction to the diagnosis of typhoid fever. It was prophesied at that time that serum diagnosis would in the future be applied to many other diseases besides the enterica. Of the more recent advances in the application of serum diagnosis to the detection of infectious processes being at work, none promises to be of more importance than the serum diagnosis of syphilis.

Statistics show that next to tuberculosis, syphilis is the most important cause of death in man. In 1906 Wassermann, or, more properly speaking, Wassermann, Neisser, and Bruck, first described a method of diagnosis of syphilis by means of the blood serum. This reaction occurred between the serum of syphilities and a watery extract of syphilitic fetal liver. This fetal liver produces a reaction of fixation in the presence of syphilitic serum, but produces no such reaction with the serum of normal individuals or those suffering from other diseases. In order properly to understand the Wassermann reaction, it is necessary to become familiar with the reaction of fixation, or what is known as the Bordet-Gengou phenomenon. Also we should understand the principle of hemolysis. Bordet and Gengou in 1901, five years previous to the description of the Wassermann reaction, found that when bacterial emulsions were injected into animals they were rendered immune to the particular bacteria used. Bacterial emulsions were called antigens. Animals injected with these antigens developed certain defensive bodies known as antibodies in their serum, in the process of becoming immune. Wassermann, in his modifications of these phenomena, substituted bacterial extracts instead of bacterial emulsions. Hemolysis is the power possesed by the serum of one species of animal to dissolve corpuscles of another species of animal. Hemolysis shows an absence of antibody in the serum of the patient, while absence of hemolysis shows the presence of specific substances, and therefore the presence of specific infection.

Although it is not my desire to inflict upon the members of this society burdensome detail of technique, much of which is of value only to the pathologist or laboratory worker, still I deem it important for the benefit of those gentlemen for whom this society is presumed to be instituted, as well as for those members of the society who are not familiar with Wassermann's reaction, to review briefly its technique. We must keep in mind cer-

*Read at a meeting of the Medical Society of the New York Polyclinic, November 1, 1909.

tain terms: antigen = bacteria, antibody = result of bacteria, complement present in all normal blood serum, its office being to complete the action of what pathologists know as the amboceptor, so-called because it has an affinity on the one end for antigen, and on the other end for complement.

I will now give the technique employed by Swift, of the Carnegie Laboratory, to whose courtesy and ability I am very much indebted in my experiences along this line. Various materials used are: (1) Suspected serum obtained by venous puncture or from the finger or ear. The blood is allowed to clot, and the clear serum is removed, then heated to 56° C. to destroy the complement. (2) Complement of guinea pig serum. (3) Antigen, alcoholic extract of fetal syphilitic liver. (4) Red blood cells of a sheep or other animal, freed from complement by careful washing with salt solution. (5) Hemolysin, consisting of blood of the rabbit, the animal having been injected three or four times with the washed red blood cells of the sheep.

Two tubes with following contents are prepared: Tube 1, antigen, extract of liver of syphilitic fetus, plus serum to be tested, plus complement of guinea pig serum; tube 2, red blood cells of sheep, plus hemolysin. Contents of tube 1 are incubated for one hour, then added to tube 2, and then put in the ice chest over night and the results are read in the morning. If the serum from tube 1 had come from a syphilitic individual its relation to the antigen would be a specific one, and complement would be absorbed thereby. So that when the contents of tubes 1 and 2 were mixed, no hemolysis would occur. If the serum was not from a syphilitic individual the complement would not be absorbed, but would remain active to cause hemolysis in tube 2.

Hemolysis as observed in the test tube is a tingeing of the contents a transparent red color, the red blood corpuscles being disintegrated and hemoglobin liberated. If hemolysis has not occurred the red blood cells settle to the bottom of the tube. Numerous controls are necessary to show that the antigen or serum when used alone does not inhibit hemolysis. Also sera that have previously shown positive and negative results, respectively, must be introduced if the investigator is at all conscientious. It will thus be seen that the reaction is cumbersome and exceedingly complicated, and will probably always remain a laboratory test.

Noguchi, of the Rockefeller Institute, has described what promises to be a much simpler test, and in experienced hands posseses a good deal of reliability. It is a modification of the original Wassermann test in that the relative quantity of the different factors—complement, ambocepter, corpuscular emulsion, and antigen—are known and definite. Reagents are employed in liquid form, or the various reagents are preserved in stable form upon dried filter paper ready for use. The quantity of blood serum required is small. It has been hoped that this modification might prove of value as a bedside test.

Both of these methods are still in their infancy, and the technique not yet perfect, yet they have given to us a large amount of positive diagnostic data. Many investigators have adopted various modifications of Wassermann's method. Each has its advantages in different hands. It would seem that each observer should select some method and adhere to same.

In passing on to the clinical value of the Wassermann reaction, I have reserved to myself the right to maintain a neutral ground, preferring to submit to you for your consideration some of the experiences and conclusions of some of our most noted and able American investigators. Many of the contributors to the literature thus far have been laboratory workers rather than clinicians. We must not expect the laboratories to do all the work. They must be assisted by the clinicians. At the present there seems to be a wide range of opinion regarding its value, from the boundless enthusiasm of the non-critical admirer to the growling pessimist who will not lend his aid nor recognize the value of any new method until it is completely analysed and investigated, properly labeled, and handed him on a gold plate for his use.

The history of bacteriological research in the past is full of illustrations of this proclivity on the part of medical men to be slow in recognizing many of the most valued aids to diagnosis and therapeusis.

The triumphs of Lister, Pasteur, and Koch all shared in this apathetic indifference in their early history. Between extreme optimism and extreme pessimism there should be established a middle or judicial ground. In the latest report of Gay of the Harvard Medical School, which is one of the most recent contributions upon the subject, he has attempted to cover all the literature upon the subject for the past three years. This comprises over 220 articles. The observations cover some four or five thousand cases of syphilis. Since these reports came from a dozen different sources, with probably a variable technique, it is surprising to note the uniformity of opinion regarding the accuracy of this means of diagnosis.

Estimates were given of the diagnosis in the various types of syphilis in the following percentage: Primary syphilis, average estimate of positive percentage of reaction, 75; secondary syphilis without symptoms, 75; secondary syphilis, with symptoms, 90; secondary syphilis, average percentage, 71; general paralysis, average percentage, 81; tabes, average percentage, 67.

These observers likewise examined about six hundred controls from normal individuals and from those suffering from other diseases, and with the exception of two diseases, scarlet fever and leprosy, all the cases gave a negative reaction. This shows that although the reaction as yet may not be absolutely specific, it is certainly of great diagnostic value.

Butler of Chicago, in his report, where he refers to finding the reaction positive in cases of scarlet fever, as well as in cases of leprosy, states that the inhibition of hemolysis was but slight in comparison with the complete inhibition in syphilis. In any event these two diseases would hardly come in conflict with syphilis in differential diagnosis. Swift points out that those cases in other diseases than syphilis, where a positive reaction is obtained, speak most strongly for the use of syphilitic organs in the test.

Max Nonne of Hamburg was one of the first to make use of the reaction in neurological practice, but maintains that spinal fluid should also be tested for verification. Neurologists appreciate the importance of any method that will enable them to state positively whether a suspicion of syphilis is justifiable or not.

Prof. Pritchard very aptly stated in his paper on "Neurological Syphilis," read before the Tri-State Medical Society and printed in the *Polyclinical Journal*, Vol. xii, No. v, that a neurologist is one who

knows all about syphilis and a little about neurology. That this maxim is undeniably true any neurologist will admit, and he will further admit that one of the first things that he is on the lookout for, while attempting diagnosis, is whether or not there is a syphilitic taint in his patient. This is often difficult to determine in the absence of symptoms. In fact, it is a practice among many neurologists, based upon results of experience, to treat a large number of diseases of the nervous system by anti-syphilitic remedies. In making a diagnosis it has to be determined by signs bearing a direct casual relationship to the nervous symptoms for which the patient is asking advice. The patient's remembrance of onset, duration, and course of the symptoms is often imperfect and vague. They often cannot or will not remember. Such facts as they can remember are often the same as in cases of so-called neurasthenia, and are misleading. In many cases, especially in women, there may be no history of syphilitic infection or no signs on the body, and yet the character of the disease may clearly point to the possibility of syphilitic origin. We may treat a patient by antisyphilitic remedies and he may recover and still we have no proof that the patient has had syphilis. A person suffering from an affection of the nervous system, giving a positive Wassermann reaction, is much more liable to be suffering from syphilitic affection than one who is admittedly syphilitic, but has shown no signs, owing to treatment. Heretofore we have had no reliable diagnostic measure in cases where no symptoms are present and infection is denied. Cases under treatment show a positive reaction much less frequently than those untreated. While a positive reaction indicates that the individual has had syphilis, it does not necessarily prove that the particular lesion from which patient is suffering is syphilitic. It is a well-recognized observation in neurology that exactly those cases of syphilis that run a mild course and clear up early are often later the subjects of tabes or general paresis. The virus may have a selective action upon the cerebrospinal system. Wassermann was led to the hypothesis that long years of antibody production on the part of the nervous system lead to pathological degeneration of it. The presence of these antibodies in the serum of syphilitics may be irrespective of length of time that has elapsed since the first infection. Sachs believes that although much stress has been laid upon the value of the reaction in the diagnosis of tabes and general paresis, its principal value lies in its corroboration of our belief in the syphilitic origin of these two diseases. In cases presenting symptoms of either general paresis or tabes, but not marked, or marked by symptoms of so-called neurasthenia, the reaction might prove valuable. We must not infer, however, because a patient possesses neurasthenic symptoms, and it is proved that he has had syphilis, that he will develop general paresis. He may have been well treated early in the disease and his present symptoms be due to other causes. The reaction would throw much light on these obscure cases. Sachs believes that the reaction may prove of more value in the diagnosis of a number of other conditions, namely, between multiple sclerosis and cerebrospinal syphilis; central gliosis and specific myelitis; in cases of intracranial pressure, whether due to malignant neoplasm or to syphilitic gumma. In cases of epilepsy and hemiplegia, it would always be a matter of scientific interest, if not of therapeutic value, to know if the cause was specific. Butler's conclusions, based upon experience, are that the reaction is positive in 100 per cent. of cases of primary syphilis and in 95 per cent. of secondary syphilis. In tertiary and latent cases, parasyphilitic diseases, and visceral syphilis, he believes the reaction positive in 60 to 75 per cent. of cases. He believes with Swift that the reaction may be made a reliable guide as to treatment, since such reaction is influenced by treatment. A positive reaction would indicate activity of the specific virus. A negative reaction is therefore not of necessity of negative value. The patient's destiny may thus be controlled. He may be protected from the serious ravages of late syphilis of internal organs, or possibly the parasyphilitic affections, by the institution of vigorous antisyphilitic treatment.

Although we have a valuable therapeutic aid, we have not had a satisfactory diagnostic measure. In skin lesions where syphilis is manifestly present it cannot have more than a confirmatory value, and the fact that the reaction is found positive so frequently in this condition renders its use in more obscure cases a fairly certain diagnostic sign. There are a number of irregular skin manifestations that cannot surely be diagnosed as syphilitic. Formerly the therapeutic test was applied when such condition presented itself. The Wassermann test might justify our suspicions, and proper treatment could be at once instituted, thus saving valuable time. If negative reactions were obtained, the saturation of the system with damaging drugs might be prevented. Butler again draws our attention to the difficulty of diagnosing visceral syphilis. If gummata exists they are often located so that they do not interfere with the function of any organ, and may be out of reach of the palpating hand. Syphilis of the liver often resembles in symptoms malignant growths of same, which are inoperable. There may be no history or evidence of past syphilis. Lesser, in his post-mortem studies of visceral syphilis, found thirty cases of liver gumma that had gone unrecognized clinically. Very many cases of gumma of the heart and lungs are never diagnosed. We thus have in the Wassermann reaction what would seem a valuable aid to the surgeon and internist, valuable especially in early diagnosis. Knowing the wide prevalence of syphilis as an etiological factor in a large number of visceral conditions, it should receive consideration and the blood be examined for reaction.

Castelli, after reviewing the subject at length, makes a plea for the recognition of the value of the reaction from a social standpoint. Unrecognized and untreated cases of syphilis creating degeneracy and insanity, it puts us in position to advise more scientifically upon the question of marriage. He believes that in addition to its value as a tremendous factor for benefiting our fellow-beings, it might become an important factor in dispensation of justice where we could recommend courts to leniency in those cases where previous syphilitic infection had produced a derangement of mental poise.

In drawing to a conclusion this rather chaotic arrangement of experiences and opinions, I realize that many important considerations relative to the reaction and its value may have been omitted, not by intent, but through lack of time and space. My own experience with the reaction has taught me that in the study and analysis of groups of cases submitted to the test some discrimination is necessary, as in the analysis of any symptom. In my opinion the clinical value is well established, but it is difficult sometimes to find a satisfactory scientific

explanation. The controversy has already assumed voluminous proportions. The unwary reader is tempted to feel that the test itself must be a doubtful one, in view of the differences of opinion that exist as to the details of its explanation. The specificity of the test is the matter of paramount importance. The uniformly negative results found in controls and a large percentage of positive reactions in leutic, or even suspiciously leutic cases, tend to establish the reliability of the test. It is upon these two points that the reliability of any blood test depends.

If we will regard reaction as a symptom and measure it in the same light as other symptoms, we will appreciate its true value. Physicians should recognize in the Wassermann reaction a valuable addition to their armamentarium, become thoroughly conversant with its possibilities, and utilize it at every opportunity.

A CASE OF TUBERCULOSIS WITH PERIODICAL HEMORRHAGES FROM THE BOWEL.

By DAVID I. MACHT, A.B., M.D.,

BALTIMORE.

Menstruation, powerfully as it affects the entire constitution of even a healthy woman, exerts a much more marked and detrimental influence on the body in impaired health. A great many diseases are aggravated in catamenia, but perhaps in no other disease is the impress made on the course of the malady by menstruation more clearly and strikingly exemplified than in the case of tuberculosis, and especially of pulmonary tuberculosis. The increase in blood-pressure, the changes in metabolism, the congestion of the internal organs, and other accompaniments of the monthly sickness, as described by Riebold and others,[1] all play their part in modifying the progress of the disease, so that in studying a case of tuberculosis we cannot help being struck by the periodic recurrence of certain signs and symptoms directly referable to menstrual molimina. We note an increase of pathological physical signs, such as the multiplication and accentuation, and sometimes even the development of râles; we find, very frequently, a premenstrual or a menstrual rise of temperature; we observe an aggravation of certain symptoms, such as cough and expectoration. G. Daremberg,[2] Jean Noncher,[3] Heimann,[4] and others have emphasized this so-called Cyclical Cause of Tuberculosis.

Among the most interesting phenomena elicited by the menstrual state and not so infrequently to be observed in tuberculous patients are the so-called "vicarious" hemorrhages. I have observed at least half a dozen patients in the Phipps Dispensary of the Johns Hopkins Hospital with periodic hemoptyses occurring either simultaneously with, or taking the place of, the menstrual flow. Various observers have reported similar cases.

It has been my good fortune recently to study a patient with a rather different form of periodic hemorrhages, namely those from the bowels. The case is rare and interesting enough, I think, to be worth reporting.

History: Miss E. D.; private patient; 30 years old; American; designer. On March 13, 1908, patient came to me complaining of a chronic "cough."

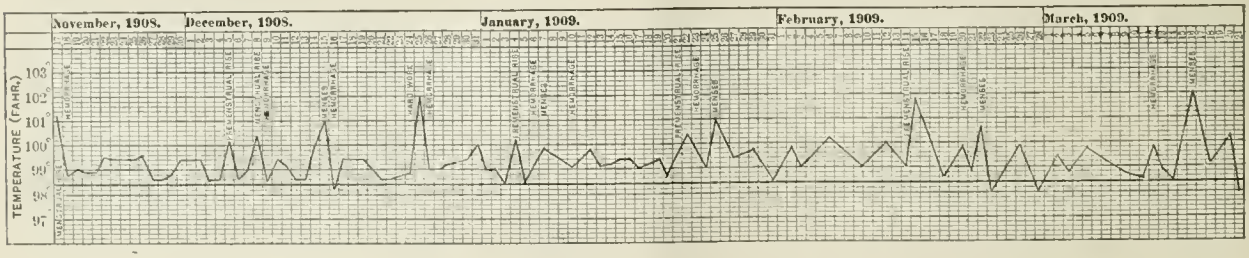
Family History: Father living and well; mother died recently of consumption at age of 44 years; one sister also died of tuberculosis; one brother died of tuberculosis; two brothers living and well. No other history of tuberculosis in the family.

Past History: When a child, patient had measles, mumps, and diphtheria; suffers occasionally from tonsillitis; had pleurisy nine years ago. No diseases of any other organs. Habits good.

Present Illness: Patient has been ailing for some months, losing flesh, and getting weak. About two and one-half months ago she caught a cold; since then has had a slight cough at night, which gets worse in the morning. Has slight yellowish expectoration, with garlic-like smell. Is not spitting blood now, but did have several hemorrhages about a year ago. Is short of breath on exertion; has night sweats, and has lost some weight. The appetite and digestion are fair; the bowels regular. Has occasional palpitation of the heart. No swelling of the feet. No trouble with micturition. Has noticed no fever or chills.

Periods come a little too soon and are very profuse, lasting 7-8 days. No leucorrhea.

Physical Examination: The patient is about 5 feet 8 inches high; weighs 131 pounds. Temperature, 98. Pulse, 100, rather small and irregular in rhythm. Respiration, 20 to minute. The patient is fairly well nourished; looks rather pale; tongue clean; throat shows a rather enlarged and reddened left tonsil and a slightly congested



pharynx. The glands of the neck are not enlarged.

The chest is fairly well formed; long and flat; both clavicles are slightly prominent, the left a little more than the right. The left scapula is more prominent than right. Vocal fremitus is increased on both sides of chest. On percussion, the note is distinctly impaired at left apex, and down to third rib in front and over left supraspinous fossa in back. There is slight dullness at right apex. On auscultation the breath sounds are impaired on left, harsh in quality, with prolonged expiration; and on coughing fine moist crackling râles are heard. The breath sounds at right apex are harsh and exaggerated, and on coughing fine moist râles are here also elicited. Heart: Point of maximum impulse is in fifth interspace, inside of mamillary line. Cardiac dullness not increased. The sounds are clear; there are no murmurs; there is an occasional reduplication of first sound at apex. The abdomen is natural; the liver and spleen not enlarged. Slight tenderness in right groin.

I gave the patient the skin and eye tuberculin tests and ordered her sputum examined. The skin and eye tests were positive, and the sputum was found to contain a few acid-fast bacilli. These findings led to the diagnosis of pulmonary tuberculosis.

I have had occasion to examine the patient a little later, on April 5, at her menstrual period. The patient at that time had more cough, was running a slight fever temperature, and was in general more sick. The physical signs in the chest were also more marked.

About two months later the patient complained to me of pain in back and in right side under the ribs and of hemorrhages from the bowels. These hemorrhages, she said, were especially liable to occur at the time of her menses, and greatly weakened her. On examining the patient, I found tenderness on pressure in the right hypochondrium. The urine and stools were ordered for examination. I found the urine normal; no signs of albumin or sugar. The stool contained considerable dark red blood and had a foul smell. On microscopic examination, I did not succeed in definitely demonstrating tubercle bacilli.

I have had occasion to watch the patient for many months afterwards, and found the course of events something as follows: The patient between periods feels tolerably well, and though working runs but a slight temperature. With the approach of the menses, she begins to feel more sick, the appetite grows worse, she has headache, and pains in back and in right and left hypochondrium. There is a premenstrual rise in temperature, and patient also runs a higher temperature during her menses. At the time of her periods, she gets severe cramps in the abdomen, especially in the region of the hepatic and splenic flexures of the colon, and under colicky pains passes considerable quantities of more or less pure blood.

Such a hemorrhage at one time, on July 26, 1908, amounted to about half a pint, and weakened the patient exceedingly. I found her hemoglobin, by Tallquist paper, to be about 70 per cent. A rectal examination gave no clue as to the cause of the hemorrhage. There were no signs of hemorrhoids whatever.

The whole history of the case, with the physical and chemical findings, led me to make a probable diagnosis of tuberculous ulcers of the intestines.

I need not dwell here on the therapeutics of the case. I tried almost every remedy recommended, both by mouth and per rectal injections, with very little success. The patient was then sent to the country, where her general condition improved; but when I heard from her last, she stated that the hemorrhages, though not as severe as they used to be, still continue.

The chart here drawn shows the temperature curve of the patient, and gives a picture of the periodic rises in temperature and accompanying hemorrhages from the bowels.

TREATMENT OF CARCINOMA WITH THE BODY FLUIDS OF A RECOVERED CASE.*

A PRELIMINARY COMMUNICATION.

By EUGENE HODENPYL, M.D.,

NEW YORK.

PATHOLOGIST TO THE ROOSEVELT HOSPITAL.

About four years ago the writer became interested in a case of carcinoma of the breast in a woman then 37 years of age. The clinical history and the morphology of the tumor were typical of a rapidly growing malignant cancer. In spite of radical operation, multiple recurrences appeared in the neck and in the primary scar. After the thorough removal of these, secondary growths appeared which were morphologically typical of rapidly growing carcinoma. Still other tumors developed in the neck and breast, which, owing to local complications and the debilitated condition of the patient, were not removed. Later large tumors developed in the liver, which nearly filled the abdominal cavity, followed by the occurrence of excessive chyliform ascites. The prognosis was unqualifiedly bad and the patient's death seemed imminent.

But, nevertheless, the tumors in the neck and breast gradually dwindled and disappeared. The abdominal tumors gradually grew smaller and became imperceptible, while the liver became smoother and smaller. At length about four years after the first operation the liver is approximately normal in size and position. With the exception of the scars and decreasing emaciation, and extreme chyliform ascites, requiring frequent tapping, there is now no indication of the original disorder.

In his deliberations upon this rare case of recovery from extensive carcinoma, with residual chyliform ascites, the writer was led to weigh the possibility, so often discussed especially in connection with experimental tumors in mice, of the development by the patient of some sort of antibody inimical to the progressive growth and persistence of the tumor cells. The alternative hypothesis, which seemed plausible, was that in the processes of tumor-tissue formation in the abdomen, some physical or physiological disturbance of organic or internal secretions might have occurred, leading to the accumulation or formation of substances antagonistic to tumor cell growth or existence.

The ascitic fluid having been freely placed at the writer's disposal to test these theoretical conceptions, a series of mice, which had developed tumors after the implanting of some of the well-known

*Received for publication February 19, 1910.

strains of mouse cancer cells, were injected with varying amounts of the ascitic fluid. These injections were made near the tumors, into the tumors, and into the body at large. The effect of these injections, in brief, was to lead to marked necrosis of the tumors, to a noteworthy diminution in their size, or to their complete disappearance.

After experimental tests of the harmlessness of the fluid, first in animals, then in human beings, injections of the fluid in cases of carcinoma of various types in man were undertaken. These injections have been made in small quantities, near or directly into the tumors, or in large quantities into the veins. The general effects of these injections in man has been nearly uniformly to induce a temporary local redness, tenderness, and swelling about the tumors, which soon subside. Then occur softening and necrosis of the tumor tissue, which is now absorbed or discharged externally, with the subsequent formation of more or less connective tissue. In all cases, the tumors have grown smaller; in some they have disappeared altogether. In no instance has any tissue in the body, other than the tumor, shown the least reaction after the injections, nor have any systemic effects been manifest even after large venous infusions.

The greater number of the forty-seven cases thus far treated were distinctly unfavorable, many of them hopeless and inoperable. Many of the cases are still under observation by the writer or by other physicians in and out of New York.

The records of the cases treated, the technique employed, and the results obtained will be placed at the service of the medical profession as soon as time permits, together with the results of various obvious control experiments which are now in hand under the direction or with the concurrence of the writer. In the meantime this preliminary communication is made, first, in order that the attention of the profession may be called to the possible significance of body fluids from the rare cases of those who have recovered or are recovering from carcinoma; second, to correct the false impressions which may have been conveyed by the premature and unauthorized news items in the daily press; and, finally, to secure an opportunity to remind physicians practically interested in this study, that the urgency for this treatment, of hopeless inoperable cases, is hardly just, either to these patients themselves or to a method from which it is hoped to secure new resources and new light through deliberate and reasonable tests.

It is not my purpose to announce at this time a new cure for cancer, but to call attention to the remarkable, selective necrotizing effects upon carcinoma cells of the ascitic fluid from a recovered case of carcinoma, wherever in the body of the patient this fluid is introduced. The nature and significance and the practical importance of the substances contained in this fluid and the ultimate value of this method of treatment of carcinoma are to be finally determined only by a continuance and completion of the various correlated series of investigations, chemical and biological, now under way, or by such tests as other observers may undertake.

Gastric Cancer.—Rattermann says: "The future of gastric cancer cases depends on early operation, and the suspicion of its presence where conditions exist must stimulate the keenest observation over a period varying from several weeks to that of many months, when 80 to 85 per cent. of the cases will be recognized or at least far enough advanced to warrant exploratory incision."—*Lancet-Clinic.*

OPHTHALMIC INSTRUMENT CASE, STERILIZER AND TRAY COMBINED.

By MAX TALMEY, M.D.,
NEW YORK.
SURGEON, HARLEM EYE, EAR, AND THROAT INFIRMARY.

When performing major ophthalmic operations at the patients' homes I frequently met with annoying difficulties and lost a good deal of time. The instruments had to be transferred from their case into the sterilizer and thence into a tray to be handy for the operation. Sterilizing delicate surgical instruments in a household not adapted for the purpose is a task bothersome to all, to the family no less than to the surgeon. I have therefore devised an ophthalmic instrument case to serve also as a sterilizer and a tray and which can be handled even roughly without any injury to the instruments. Such a case first of all does away with two transfers of instruments when they are sterilized in the house of the patient. The instruments properly arranged in the case are boiled herein and not removed until they are used directly for the operation.

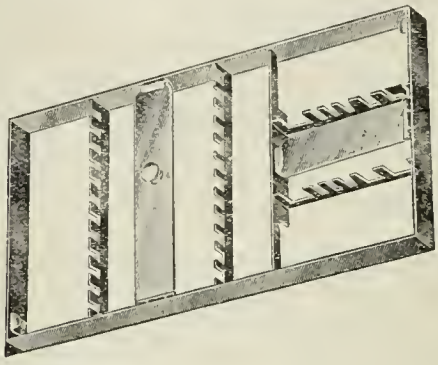

Fig. 1.—Rack with springs in place without the instruments, showing the two compartments, the separating band and the dentated cross bands.

The greatest advantage of the case, however, lies in its rendering sterilization in the house of the patient unnecessary. The following procedure, which I usually practise now, is feasible by means of the case. The instruments are boiled in the case at the surgeon's office and then instruments and case are dried with a sterilized cloth. The instruments are now put back into the case in their proper order, the case is wrapped in a sterilized towel, and the package taken to the home of the patient. Here there is no need to handle the instruments any more before the operation. After preparing the patient the sterilized towel is spread on a table near the bed, the case is opened, the springs holding the instruments in place are loosened, and the operation may begin.

The exact construction of the case is shown in the accompanying drawings (Figs. 1 and 2). The general features of the implement are the following: A rack carrying the instruments fits tightly into a box and can be easily lifted out of it by two hooks attached near two opposite angles, together with all the instruments which remain undisturbed in their places. The rack has two compartments, each with two dentated cross bands (Fig. 1), on which the instruments are resting, held in their places by two springs parallel with the bands. The compartments are different in size, one being 142 x 112 mm., the other 112 x 72 mm. They are separated by a band on the lower side, of which a rectangular piece is cut away at each end, thus pro-

curing two windows. Owing to this device three scissors, instrumnets usually difficult to place on account of their rings, can be put in one interspace of the cross bands in the smaller compartment, the rings fitting partly into the windows.

Since the instruments are resting on a removable rack it is not necessary to use the box for sterilization, but the rack alone with the instruments in their places may be boiled in any kettle.

The box, 214 x 112 x 21 mm. in size, consists of base and cover (Fig. 2). When the case is closed, the cover overlaps the base 5 mm. and both are

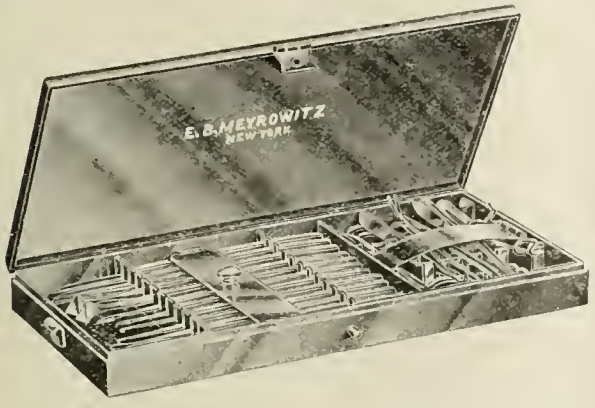

Fig. 2.—Open case containing the rack, showing the instruments held in their places by the springs.

firmly held together by means of hinge and lock. Two hooks fastened to the short sides of the base serve for lifting the case. When closed the case can also be lifted by a handle attached to the cover.

The case, although of small size, has room for 20 instruments sufficient for any operation on the lens and iris, and the instruments are not crowded. The larger compartment of the rack may contain: Two cataract knives, 2 keratomes, 2 discission needles, 1 iris hook, Tyrell's double, sharp and blunt; 1 cystotome, 1 cystotome and Daviel's spoon, 1 lens snare, 2 iris spatulæ. Into the smaller compartment of the rack may be put: One eye speculum, 1 de Wecker's scissors, 1 fixation forceps, 1 iris forceps, 1 capsule forceps, 1 curved scissors, or coagulum forceps, 1 Stevens' scissors, 1 straight probe pointed scissors.

I am indebted to E. B. Meyrowitz for the construction of the case after a pasteboard model.

55 West One Hundred and Twenty-sixth Street.

LETTERS TO A NEUROLOGIST.

By JOSEPH COLLINS, M.D.,
NEW YORK,
PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

V.

My Dear Doctor:—

I have been reading some of your "Letters." What strange experiences you must have had with patients. They are almost as strange as those I have had with physicians. When I write my memoirs, I intend to devote nine chapters to what physicians have said to me. That part of the book I shall name "The Bedside Manner, with a Few Side Remarks on the Office Manner as Well."

I am what may be called an expert patient. I am a neurotic of vast experience, and on the Resurrection Day it will be impossible for me to rise "altogether," so to speak, unless the final trump has power over laboratory bottles.

During a long and somewhat roving life, divers and sundry physicians of all schools and kindergartens have attended me. Experience teaches me that there are but two kinds of physicians: those who ought to have been something else; and those who ought to have been twins. Both kinds almost invariably wear beards. I have never understood why, unless it is taught in medical schools that drawing a beard through the hand is an impressive gesture, likely to convey to the patient that his case is under consideration by a mighty intellect. I have seen a physician come into a scarlet fever ward clad in a long, linen gown, his bald head protected by a linen cap, but with his beard flowing free. Perhaps germs respect beards. The general public certainly does.

The first bedside manner I recall belonged to a physician of the calomel and quinine school. He was a jocular person. He used to come in gaily, pinch my nose and ears—I think clinical thermometers had not been invented at that time—and say, "Tut! Tut! This won't do." It seemed quite useless to protest that I hadn't been supposing it would do. He was not a person one could argue with. His next question, asked with an air of suspicion, was, "What have you been eating?" This always made me feel guilty, for I had no way of concealing from him that I had partaken of food. I will say for him, however, that he sometimes varied his "Tut! Tut!" by "Well, well, what have we here?" I used to think that by concentrating his mind on the matter, he might find out that he had a patient there, but I never ventured to say so. He was the "family physician" of my native town, and since his death the place is noted for longevity and a low birth rate. Nobody quite likes to take the responsibility of going out of the world or coming into it without Dr. B.'s permission. When last I saw him he told me, with the air of accusing me of arson, that I was nervous. Biliousness seemed to involve no moral turpitude, but if he called one "nervous" he would be adding presently the accusation of "hysterical," and being hysterical was a capital offense. His last treatment of me was for a violent attack of spasmodic asthma. I have never had a clear conscience since, for I knew he had discovered that I had been guilty of appearing at dinner in elbow sleeves.

There is, perhaps, no bedside manner that is quite suited to asthma unless it is accompanied by a dose of cyanide of potassium. I recall one young physician who, being sent for suddenly, insisted on fanning me. When one is getting almost no breath at all, a flutter of air will take away that little, and loose ends of hair fanned into one's mouth are not a pleasing substitute. The same young man inquired of me what treatment was usually given to me, and I was obliged to gasp out, "The usual treatment in such cases." This seemed to help him out tremendously, and he begged me not to be alarmed, since such attacks are never fatal." "Unpleasant," he said (as if I hadn't already gathered as much), "but never fatal." One of the ought-to-have-been-born-twins physicians would have said, "Cheer up. You'll be comfortably dead in a minute."

I must not neglect to mention a very important physician who always thought of his patients by number. When one entered his office for perhaps the twentieth time he would glance up from his desk and begin at once to look for one's record in a large book he kept. Arriving at No. 5,386, he would say, without looking up, "What is the trouble"? Perhaps it was fifteen times that I patiently detailed

my symptoms. Each time he wrote them down in his book, gave me a prescription, and, without further remark, rang for the next patient. There was always that in his manner which made me feel that by asking what my trouble was I should be committing a grave breach of etiquette. On perhaps the sixteenth visit—I was going to him not to have him ask me, but to have him find out what was wrong—when he asked me, "What is the trouble"? I replied, "Paralysis of the tongue." This surprised him so much that he positively shut his book.

His bedside manner always made me select the largest room I had to be sick in. He always sat in the farthest chair and looked at me as if he hoped I'd disappear. I never knew him to seem human except once when he called to look after an abscess in my ear. He told me then that an abscess in the ear is the most acute agony one can endure. I found out afterward that he'd had one himself.

No man who frowns and wears a silk hat should ever be allowed to practice medicine. Such an one attended a child of mine in a severe case of measles. The frown so disturbed me that I asked him to bring a colleague in consultation. The colleague had red hair and as he sat, watching the child, he twirled a straw hat in his hands. This reassured me completely. Nobody would twirl a straw hat in the face of death.

No man who is short of breath should be a physician. Nothing is more exasperating than a series of gasps from a doctor. Any physician who crosses his legs and waves one toe up and down ought to be boiled in oil. Five minutes of watching that toe wave would induce a nervous prostration in Sandow.

Perhaps the most extreme form of bedside manner belongs to a physician I shall call Dr. X. His touch at the door bell was gravity itself. He stepped solemnly and safely to my room, but before he entered, I heard him asking for water and a towel in a subdued voice. As he came in, he glanced at the side of the bed, as if to assure me that so modern a man would never dream of such an enormity as seating himself there. He lifted a chair to the bedside. I could hear him thinking to himself, "I shall do nothing to irritate the nerves." He took my pulse and temperature with the manner of a clergyman administering baptism. I do not know what questions he asked, the only near-English one was whether I experienced discomfort in the gastric region. I felt abashed to think that I had been on the verge of saying the word "stomach." I recall, too, that he inquired whether I allowed myself much nitrogenous food. The rest of his questions I might understand if I had time to take a course in medical terminology, but at that time I was not at all sure whether "proteids" meant a disease or something to swallow. He was really a most thorough man. On rising in the morning I was to have six pitchers of ice water and six pitchers of very hot water poured in alternation down my spine. This was to shock something, possibly myself. Then I was to have what is called "gastric lavage" and take hydrochloric acid through a glass tube. In case these simple treatments should make my head ache, I was to have bromide. I was to take "nourishment." I forget what it was, but experience has taught me that nourishment is never good to eat. The fainting attacks which invariably came on about the glass-tube time, he told me were doubtless hysterical, though they might be due to something more serious with a long name. I will say for his treatment that it was eminently successful as a flesh-reducer. He charged me above all not to let anything prey upon my mind and to be cheerful.

This well-trained young man lived at some distance from my home. One morning, on fainting, I fell backward and nearly removed the metal handle of a bureau with the back of my head. A member of my family, after asking me how I came to fall, sent for the nearest doctor. He was a homeopath and several things beside, which I am too polite to call him. It was his habit, as it is the habit of another homeopath whom I have met, to do all his thinking aloud. He looked at the cut in my scalp and discussed with himself whether he had better shave the head and stitch the wound or merely paste it together. What worried him most seemed to be the fact that he couldn't attack the cause. I listened to the discussion, till I felt justified in rising to a question of privilege and mentioning one of the things he was. He remarked that I seemed excited, and made me a neat gauze turban, scented with iodoform. Iodoform does not seem to be homeopathic. Perhaps if it had been another time of the day, he would have used something else. In homeopathy, when one coughs at 10 o'clock at night, it is a fatal error to give the remedy which is indicated by a cough at 4 a. m. I asked for something to relieve the pain, and he asked me if I did not consider it nobler to endure pain than to seek relief in opiates. He told me also that it was my duty to my family to recover my health, his idea being, apparently, that I was being ill just out of spite.

The idea of bearing pain nobly is not, however, confined to homeopaths. To my mind, all a physician should expect of a patient is that he obey directions and hold still while things are being done to him. I conceive it to be the patient's right to howl as much as he pleases. One physician out of three says, "Now, be brave." Nothing is more odious, unless it be to have a physician say, "Why, I took a man's foot off yesterday and he didn't make as much fuss as you're making over having this boil lanced." Without discussing the relative pain of amputation and opening a boil, it is never any comfort to hear how much worse things have happened other people. The medical profession as a whole has still to learn this.

There is a very common bedside manner that is marked by extreme sympathy. It is usually accompanied by a pudgy hand; one pudgy hand holds the hand of the patient, and the other pudgy hand pats it soothingly, while the person to whom the manner belongs murmurs smilingly, "There, there, don't be alarmed; we'll take care of you. You're not going to suffer." I have frequently noticed this manner in etherizers. The same bedside manner belongs to the physician who won't tell you at what hour you're to be operated upon, but, going outside the door, whispers to the nurse.

In regard to operating-room manners, I have been obliged to tell a surgeon or two that hearing is apparently the last sense to succumb. It is not pleasing to hear the etherizer say, "She's going off very fast." "She's almost under." "You may as well get ready, doctor." Neither is it helpful when in extreme pain one expresses a wish to die, to be told, "Oh, you mustn't talk that way. You don't want to die."

Nobody in pain wants sympathy. He can give himself all he needs. He merely wants the physician to do something for him and to do it quickly.

I should like to record the most delightful com-

pliment I ever received. A surgeon called in a second surgeon before removing some of my works. They had what is called a consultation over me. This consists in the first surgeon saying what the trouble is, and the second surgeon agreeing with it. (It's a little different when three medical men are present. In that case they argue a little, but after they've whispered in the hall awhile, two of them always come back and tell you that the first was right.) This second surgeon I am speaking of, stood up and beamed down on me approvingly; "I like your looks ever so much," he said. It was a delightful moment, considering my age, my illness, and the way my hair was done. I was cheered at the thought of dying, believing that someone liked my looks. "For our purposes," he added, "you'll make a splendid subject."

A very uncommon bedside manner is one that seems apparently to go best with those who specialize in stomach troubles. This is what I may, for brevity's sake, call the "nearly-bored-to-death manner." I shall never forget the day I first experienced it. "What is your name, madam?" with a falling inflection at the end of the sentence, as if about to extinguish the flame that was burning dimly within him, although my card was lying on the table before him. Whenever I volunteered any information, or attempted to tell him of the illness that forced me to come to him, he would say, with a weariness of tone and a blandness of expression associated with an atmosphere of resignation to the inevitable, "Madam, if you will kindly answer my questions. That will suffice for the information that I seek." If he betrayed any interest in me or my disorder, it was as an object to which he could apply rules that had been drafted in his mighty mind and then printed, so that his mind might not be burdened with retaining them.

I have had experience with many others. The doctor who used most to frighten me was one who was always treating patients who were "threatened" with pneumonia, or with typhoid fever, or with meningitis. He never spoke of his skill in relation to the escape of the patient from these threatenings, but his assiduity stood in direct relationship to the escape. I always supposed that when you got certain germs in your system and they developed in you, you developed that particular disease. I have learned otherwise.

There isn't anything particular for you to reply to in this letter. I thought you'd like to hear some of my impressions about physicians. I trust you will enjoy them as much as I have your impressions of patients.

Yours very sincerely,

Dear Madam.—I venture to say that although I have received much pleasure from reading your letter, it is small in comparison with the entertainment your experience has afforded you. A sense of humor is a desirable asset at all times, but particularly so when one has a chronic illness. The bedside manner has apparently been neglected by your profession, which, by the way, I assume is that of a writer. I am at a loss to understand this, as it has been a very conspicuous feature of physicians from time immemorial. How very much more interesting the lives of Cardan, Caius, or Parcelsus would have been if we had had a thorough description of their "bedside manner."

In very ancient times those who were ambitious to become members of the medical fraternity were instructed in both appearance and conduct. When Bharadyaga, the prophet, went to Thousand Eyed Indra, in Heaven, to acquire knowledge in medicine, it is said that this Deity told him not only how to play the part, but how to dress it as well. Fifteen hundred years before Christ the aspirant to our Guild was told that he should be inquisitive and observant, not covetous, zealous, or lazy. He should be a philanthropist, possess a generous heart, and his disposition should be amiable and happy. He was apprised that the indications of such qualifications are an agreeable voice, a small tongue, eyes and nose straight, with thin lips, short teeth which do not expose the gums, and thick hair which retains its vigor. He was adjured to possess a healthy body, to keep his nails and beard short, his clothes clean, and to wear shoes and a small turban. He should carry an umbrella and a stick in his hand.

Do you think his bedside manner would be suited to asthma, or would it be more adapted to hysteria? As a matter of fact, in this country at least, we are evoluting out of the bedside manner. It is entirely a volitional appanage, often a natural, but by no means a necessary accomplishment. In England, for instance, the country in which the bedside manner has its greatest development, convention prescribes the top-hat and frock-coat. A physician would as soon venture to call upon the patient without the latter as without the former. This is in marked contrast to our own custom, which is to go clad in automobile costume, riding boots, and in clothing that makes bicycling comfortable.

I am inclined to think that the conventional doctor does not particularly appeal to you, otherwise, the man who twirled his straw hat would not have made so favorable an impression. We ought to be glad that we are not shackled with purposeless convention and you will agree with me, I am sure, that the restoration of health would not be facilitated if doctors were to return to the use of the full-bottomed wig, the robe and the cane which were necessary in the time of Radcliffe and Sydenham.

I wish you had offered some suggestions as to what you consider is a desirable bedside manner. I should like to speak of it to my young physicians in the hospitals. They go out into the world of strife without any hints regarding this important matter. Unlike the profession with which we are supposed to do some team-work, there are no regular gestures, intonations or *coups d'œil* which can be used in the beginning and then improved upon as opportunity offers or experience teaches. I sincerely hope that many physicians, however, are like the immortal William Maclure, the sight of whom put courage in sinking hearts. "But this was not by the grace of his appearance, or the advantage of a good bedside manner. A tall, gaunt, loosely-made man, his face burnt a dark-brick color by constant exposure to the weather, red hair and beard turning gray, honest blue eyes that look you ever in the face, huge hands with wrist-bones like the shank of a ham, and a voice that hurled his salutation across two fields." His raiment, compared with that of the fourteenth century practitioner, as described in the Doctour of Physick in the Canterbury Tales:

> "In sanguin and in perse he clad was al,
> Lined with taffeta and with sendal,"

was less suggestive of the bedside manner than his appearance. "His jacket and waistcoat were rough homespun of Glenurtach wool. His shirt was gray flannel and he was rather vague as to a collar, but

certain as to a tie, which he never had, his beard doing duty instead, and his hat was soft felt of four colors and seven different shapes. His point of distinction in dress was the trousers. 'Some threep that he's worn thee eedentical pair the last twenty year an' a' mind masel him gettin' a tare a' hind when he was crossin' oor palin' and the mend's still veesible.'" No, my dear madam, despite the immense amount of opposing poetical testimony, dress and manner do not contribute very much to the physician's usefulness, although they may to an ephemeral success.

I am interested to hear some of the things that physicians have said to you and have said at you. I should like to be able to recount to you some of the things that physicians have wanted to say, but didn't. I recall a passage from a little book, called the "Gold-Headed Cane," which is a brief biography of five physicians of the seventeenth century in England—a passage which should receive a cordial reception by many readers. It is said that Baillie, one of the five, sometimes betrayed a want of temper in hearing the tiresome details of an unimportant story. After listening with torture to a prosy account from a lady who ailed so little that she was going to the opera that evening, he had happily escaped from the room, when he was urgently requested to step upstairs again; it was to ask him whether on her return from the opera, she might eat some oysters: 'Yes, ma'am,' said Baillie, 'shells and all.'"

You say you are an experienced patient, but I imagine that there are some experiences with the bedside manner that would be entirely new to you. Those that you have described are, I think, what might be called rather commonplace. Do you suppose in the chapter of your autobiography on the office manner you will be able to describe anything quite so amusing and "fetching" as this picture of Radcliffe, with whose name so many institutions at Oxford are now associated? He was King William's physician and a great swell. This is a description of him in his sixtieth year: "His full-bottomed wig was dressed with peculiar care; when he wore his best suit of lilac-colored velvet with yellow basket buttons, his air on the whole was very commanding. He had an elevated forehead, hazel eyes, cheeks telling of the good cheer of former days, if anything, a little too ruddy; a double chin, a well-formed nose and a mouth round which generally played an agreeable smile. When he sat in his easy chair, with his right hand expanded, and placed upon his breast, as if meditating a speech, and clearing his voice for the purpose of giving it utterance; his left wearing his glove, and resting on his side immediately above the hilt of his sword, which was a very usual attitude with him, he certainly had a most comely and well-favored appearance." Do you think that you would have had a pleasanter interview with him than with the physician who referred to you by number?

A suspicion arises in my mind that although you are an invalid of experience, you have never been very ill. If you have been, you kept reflections gained from it out of your letter. It has been my experience that it is only what I shall call dilletante invalids who pay much attention to the "bedside manner."

In reality, what you have been on the lookout for has been a doctor who could amuse you while curing you. Someone who would discuss with you the symbolism of Strauss's and Wild's "Salome"; the decadence of modern German art (if you happen to have seen the recent exposition of pictures from Germany at the Metropolitan Museum); the value of pragmatism in bringing metaphysical speculation to the test of scientific exactness and in testing theories by practice. It is apparently considered a patency of good form to talk "psychology" in society nowadays, and a certain amount of skill on the part of the practitioner to guide the conversation at the bedside of the dilletante invalid into this channel, might be received as evidence of great preciosity.

Genuinely ill patients do not care whether the doctor has culture or not; what they want him to have is experience, knowledge, and skill, and the more "businesslike" he is in the display of them, the more they like him and the deeper he impresses them. "Have you ever had a case like mine before, and have you cured him?" is the vital question to them. It does not interest them to know what the doctor's views on materialism or modernism are; whether he thinks Maeterlinck is a genius with the voice of a prophet and the divination of a seer, or a belated mystic with an inclination for the primitive and a capacity for the symbolic; or whether he has views on the meaning of good at variance with those generally held. In fact, if it comes to their ears that the doctor devotes much time to these or to a propaganda of them, or to anything else called culture, a suspicion gets into the patient's mind that that doctor is too versatile to give proper concern and care to his case and he is likely to send for someone else who is absorbed in the doctoring business.

I am not belittling culture, I am deprecating it as an aid in the practice of medicine. When we discuss the things that make life worth living, it may astonish you to hear the value I give it.

Your remark about the doctor who told you that the pain of abscess in the ear is the most acute that one can endure, is an indication to me that he was very human, despite the fact that he referred to you by number and always forgot what you had previously consulted him for. It also leads me to the reflection that the best training a doctor can have is to experience a serious illness, and for a surgeon to have a capital operation. Either one will give him as nothing else can possibly do, inside information concerning the problem with which he is dealing. It will humanize him to a degree that no amount of second-hand experience can approximate, and it will provide him a point of view in dealing with persons that no other kind of experience can furnish.

The implication in your letter that the physician makes an impression upon his patient by his manner as well as by his matter, is very true. Indeed, in some instances the patient needs more skillful handling than the disease, and frequently the latter cannot be successfully combated until the former is won over. In a large measure, this constitutes what is called inspiring and gaining confidence. I have heard that the bedside manner has very little to do with this.

As physicians we are constantly made aware of the fact that we are serving more than one master; our profession is one, our patient is another. Both are exacting. The former demands a conformity to ethical principles, some of them ideal; the latter, infallibility and the capacity to give and to give generously on every demand. That many of us fail in both does not at all mean that many do not succeed in satisfying both. Those who succeed do so by simplicity of purpose and sincerity of manner.

MEDICAL RECORD.

THE INCREASED COST OF LIVING AND THE DOCTORS.

IN a personal way, the present increased cost of living, of course, results to the material disadvantage of physicians. As part of the great unorganized majority upon which the economic burden chiefly falls, they must stand helpless as individuals and see conditions created under which the purchasing power of their incomes steadily diminishes. Lacking the solidarity of the plasterers' or hod-carriers' guilds, they have no union to scale up their incomes commensurate with the rise in beefsteak and eggs—unlike the tradesman who meets the rise in wheat and potatoes by adding a fourth to the selling price of his wares, they cannot regard their professional services in the light of a commodity, the cost of which is to vary with fluctuation on the produce exchange. Few if any are there who would attempt to readjust their incomes to an increasing outgo by adding an extra half dollar to the charge for a visit to the ailing storekeeper or groceryman. And beside depreciation in purchasing power, the income itself tends to shrink—persons who find the struggle for mere existence steadily more bitter, hesitate to deplete an already insufficient wage by calling in a doctor in the early, more amenable stages of disease, and many honest, grateful folk there are who find the new order of things an absolute bar to paying the doctor's modest honorarium. Clearly the situation is one which is of vital personal importance to the medical profession, even though its members remain capable of securing the actual necessities of existence.

But there is a large class of the public which is even less fortunate, not only those to whom the maintenance of a hand-to-mouth existence has always been a struggle, but those whose incomes, formerly sufficient for comfort, are now inadequate to provide the ordinary decencies of life. Women, whose labors should have remained domestic for the sake of the unborn future, have become conscripts in the army of industrial toilers; tender children are snatched from school and play to be stunted in body and mind by the exigencies of too early labor. Even if the medical profession is too unselfish to fight for its own advantage like the artisan guilds, yet it is its duty to champion the cause of the suffering and helpless. While others may bow to the sordid god of Business, the high calling of the physician lifts him superior to all interests save that of humanity, and this duty is even more urgent since, bad as conditions are, there is every reason to believe that they will become worse. Entrenched monopoly is loth to give over its fattening; and the rapid aggregation of wealth into steadily vaster masses means economic conditions, outside of competition, under which, without repressive measures, not only individuals but communities will become powerless. A thoughtful, dispassionate profession will, therefore, in union with all good citizens, consider the vital question of corporations, with the view of identifying and opposing such as seem to be inimical to the best interests of the community and the race.

If, as has been said, the tariff is the mother of trusts and bestows its benefits and imposes its burdens unequally and unjustly, or if it necessary to the prosperity of the country, in either case it is a subject which, from its profound influence upon the individual, society, and humanity, the doctor would do well to consider and study. When it is next subject to legislation, he should insist that its provisions be bared to the white light of publicity, and that the welfare of human beings be given as much consideration as the rights of property. The doctor should vote as he practises—for the benefit of humanity. Himself well satisfied with a modest competence as return for the exercise of his humanitarian functions, it should be difficult for mere sophistry to betray the physician into supporting any principles, groups, or individuals whose success may mean the acquisition of excessive wealth by the few at the expense of want, suffering and physical deterioration by the many.

Industrial competition is, of course, a most necessary and excellent thing in its way, for the material progress of mankind undoubtedly depends upon the fitting reward of special ability and zeal and the due penalizing of inefficiency and sloth. But these rewards and punishments must not be allowed to become excessive if the welfare of the race is to be considered. There is no harm done either to the present generation or to posterity when relative inefficiency punishes itself through inability to provide luxuries; but it becomes quite another matter to the State if rewards for success are allowed to become so excessive that punishment for failure carries with it deprivation of the actual fundamental necessities of existence and the perpetuation of a robust, healthful race. It is therefore a question, which carries its own answer, whether any economic system which permits the generations yet unborn to come into the world degenerate in body and mind as a result of the deprivation of their parents, can be approved by the physician. Aside from any menace to our national institutions, the piling up of the tremendous modern private fortune, the very vastness of which absolutely precludes the use of even a fair fraction of its income by its possessor, seriously threatens the public health and the physical efficiency and standards of the body politic. Originally, there is a fair living with reasonable comforts available to us all in this country, and it is a matter of simple mathematics to show that the aggregation of an undue proportion of the available

wealth in the hands of the few means a subtraction all along the line from the resources of the many and corresponding reduction in standards of living.

And in respect to the sociological and health problems created by such excessive fortunes the physician, in an individual way, has opportunity to work for society through his intimate professional relations with the very rich. He can honestly assert that the creation of unduly great fortunes is a benefit neither to their possessors nor to the race. Ability habitually to overindulge in costly indigestible food and drink and to avoid physical labor, combined with the excessive nervous strain of business competition and the complexities of social life, have their results in the steadily rising rates for disability and death from neurasthenia, gout, rheumatism, and the diseases of the kidneys, heart, and circulatory apparatus. The poor man, with all his ills dependent on malnutrition, fortunately escapes that of corpulency, a condition which was recently shown had never, in the experience of the two largest life insurance companies, existed in risks who survived to a good old age. Both extremes in the social scale have their special perils.

As doctors we appreciate that beyond the ability to provide for all one's physical and mental needs, the acquisition of wealth serves no useful purpose; while the corresponding deprivation under which the general public is thus made to labor has too profound an influence on the race to permit us to countenance wealth-getting as a pastime or an obsession. The collection of dollars has quite a different effect upon the community than that of the collection of postage stamps, for example. And when the man with superabundance apparently regards money-getting as a sport, like hunting or fishing, it is well to recall that particularly all our States now have laws fixing a legal limit to the bag of quail or trout; when the desire reaches the intensity of an obsession, suggestive treatment like that required for the victim of any other unhealthy idea is desirable.

Nor does the ultimate good disposition of great wealth repair the damage wrought by its accumulation. With all appreciation toward those who build hospitals, endow institutions, and donate libraries, nothing they thus do can compensate the race as a whole for the results of the less wholesome conditions and environment which continued denial of their adequate share in the rewards of industry have brought about. It would be now both impossible and unwise to give this share back—but it was an injury to the nation and race to take it away in the first place.

Finally, while standing always for material progress, the physician ought to preach the doctrine of the simple life as opposed to the useless artificialities which constantly and unnecessarily tend to render existence more complex. He can consistently set his face against the follies and extravagances which weaken the race as a whole and create conditions which favor the elimination of the social extremes. Of far clearer vision than the self-centered money-grabber, he must interpose to stop the scramble to discount, for present advantage, the future health and happiness of the nation.

THE EVOLUTION OF THE MODERN HOSPITAL.

In Europe and in England the hospital has been in being from very early times, and it would be a grave error to imagine that the up-to-date hospital had its inception solely in the brains of the present day scientific practitioner of medicine. More than two thousand years ago there were hospitals in Europe in which the sick and injured were cared for. With the institutions devoted to the treatment of suffering humanity which flourished in countries far advanced in civilization, like the Roman Empire, Greece, and Egypt, there is no space to deal here except merely to remark that it is probable that the Egyptians had a very considerable knowledge of the healing art, even when considered in the light of comparatively recent discoveries. In England and in Great Britain generally a study of the subject will quickly convince one that the evolution of the hospital there has been steady and gradual, extending over a period of eleven centuries or more. Miss Rotha May Clay has just published a work on the medieval hospitals of England, in which she emphasizes and illuminates the fact that such institutions are not the outcome of any modern philanthropic movement, but are England's inheritance for nearly eleven hundred years. In the beginning of the movement, however, a hospital was not regarded simply as a place in which the sick and injured might be cared for, because in the middle ages the word had a somewhat different, or it will be perhaps more correct to say, a far wider significance. Then hospital might mean anything from the infirmary of a monastery to a leper house. Indeed, all charitable institutions, including almshouses, hostels for pilgrims, refuges of infirm or superannuated priests and decayed gentlefolks, lunatic asylums, and orphanages, were termed hospitals. In short, the hospital played an even more important part in the social life of the dwellers in medieval times than does now the modern hospital, which was evolved from these vast foundations.

The hospital had its origin in piety, or in superstition and fear, or in all three combined. The earliest of which there is any record in England dates back to Saxon times. St. Peter's Hospital in York, and St. Wulstan's Hospital near Worcester, the former being built by Althelstan the King, somewhere between the year 925 anl 940, and the latter a century later. At the time of the Norman Conquest the hospitals were a component part of the monasteries. Every religious house had its own public infirmary, at first within the monastery precincts and later outside the walls, in the form of a separate building. After the divorce of the hospitals from the monasteries became more general, independent charitable foundations sprang up on all sides, and during the next three hundred years it became the custom, it might be said almost the fashion, to found charitable institutions of every description. In some instances piety was the compelling force, but often the desire to expiate sin, and that type of human vanity which is evident even in these days, the wish to perpetuate a name, were the levers which moved the human action.

Then came separate establishments for the sick alone, such as St. Thomas's Hospital, Canterbury. In connection with this institution Archbishop Stratford, in 1342, directed "that poor pilgrims in good health shall be entertained only for one night. . . . That greater regard shall be had for the sick than for the well pilgrims." At about this period also the necessities of parturient women began to be seriously considered and in 1414 the foundation deed of Holy Trinity Hospital, Salisbury, sets forth that "lying-in women are cared for until they are delivered, recovered, and churched." At the same time the insane were first isolated. The first English madhouse was erected near Charing Cross, but Stow, the historian, says that "sometime a King of England not liking such a kind of people to remain so near his palace, caused them to be moved farther off, to Bethelem without Bishopsgate." As evidence that leprosy was very prevalent in England in the middle ages, Miss Clay states that there is documentary proof of the existence of over two hundred leper institutions in England.

When the reformation came and when the monasteries suffered severely, to a large extent the hospitals suffered with them, and the system received a serious check. But its foundations had been laid too firmly to be wholly destroyed, and slowly but surely hospitals continued to improve, until they reached their present height of development. It must be borne in mind, then, that to the religious orders is due the credit of founding all charitable institutions, and among them hospitals, and that it is also owing to this fact that the hospitals of Great Britain are conducted on a charitable basis.

Sleeping Sickness in Uganda.

Sir Henry Hesketh Bell, late Governor of Uganda, has written recently a report on sleeping sickness in Uganda, a résumé of which was published in the *Lancet* of January 22. It is probable that more people have died directly from sleeping sickness during the past twenty years than from any disease, certainly than from any tropical disease. Uganda has been absolutely decimated by its ravages, and other parts of Africa have suffered almost to an equal extent. In some degree even now the malady is mysterious, for although it has been proven with sufficient clearness that its spread is due to the tsetse fly, *Glossina palpalis*, there are many more points in connection with its infectivity and dissemination which still need elucidation. For example, there is no agreement as to the length of time that the malevolent fly carries infection. It was formerly believed that this term was but a few days, but Sir David Bruce, the greatest authority on the matter, now states it as his opinion that *Glossina palpalis* may retain its infectivity for two years. According to Sir H. Bell, two features of the disease stand out vividly. One is its intractability to remedial or curative therapeutic measures, and the other is that prevention is the sole means of successfully coping with the pestilence. Either the tsetse fly must be exterminated or persons must be removed from infected areas. To exterminate the tsetse fly is a hopeless task. The alternative measure seemed to be within the power of the administration, and it was hoped that by placing all sick persons beyond the reach of the fly to prevent the flies from procuring the means of further infection. Eventually action was taken on the following lines: (1) The removal of all persons to fly-free areas, and their treatment by medical officers in specially organized camps; (2) the temporary removal of all healthy persons from areas infected by flies which are presumably infected; (3) the elimination of flies as far as possible in all localities from which the population cannot be removed, and in all places through which travelers are obliged to pass; (4) further investigations into the life-history of the tsetse fly with a special view to the discovery of conditions that appear to be inimical to the fly; and (5) the study of curative agencies. The carrying out of the above measures has resulted in an immense reduction of the mortality from the disease. It is estimated that between the years 1898 and 1906 more than 200,000 persons died from sleeping sickness in the provinces of Buganda and Busoga. During 1907 the deaths were about 5,000, and in 1908, 3,662. The most remarkable incident in the history of sleeping sickness is the complete failure of therapeutic remedies in the treatment of the disease. Sir H. Bell states that if an individual contracts the disease he or she is surely doomed to die. The treatment by injection of atoxyl, so warmly lauded by Koch and others, has not given the results expected. In some cases atoxyl caused blindness to such an extent that its use had to be greatly restricted. Mercury in conjunction with atoxyl seems to have given more satisfactory results, but as said before, no reliance can be placed upon any form of treatment. This being so, preventive measures are the only measures left, and thus it appears that so long as no cure is discovered the only safeguard against the disease is a rigid taboo of all fly-infected localities.

Rupture as the First Symptom of Aneurysm.

Though aneurysm of the aorta may be among the most distressingly painful affections to which mankind is heir, it not infrequently happens that extensive fusiform or even sacculated dilatations of the aorta give few or no subjective symptoms. An example of this occurred a few years ago in the wards of the Johns Hopkins Hospital. The patient, a professional gymnast, was admitted for indefinite thoracic symptoms, and was found to have a large aneurysm of the aortic arch. After a short sojourn in the hospital, however, he left of his own volition and for some weeks, during which his aneurysm increased in size, he continued in his profession of a trapeze performer, experiencing but little inconvenience from his aneurysm, though later, owing to the tumor eroding the sternum, he suffered the most intense anguish and finally died in the hospital. In such cases of latent aneurysm the diagnosis is often difficult, and may be made only at autopsy after a sudden hemorrhage, internal or external, has carried off a man apparently in perfect health. A case of latent aneurysm of especial interest owing to the location of the rupture and the resultant clinical picture is reported by J. Lloyd Roberts in the *Liverpool Medico-Chirurgical Journal* for January, 1910. The patient, a laborer in a lumber yard, sixty years of age, appeared, until the day of his death, to be in perfect health. While carrying a heavy beam, he suddenly became faint and fell to the ground, but did not lose conscious-

ness. On admission to the hospital he was cold and collapsed. There was no dyspnea. The pulse was fairly good, regular, varying from 80 to 90 per minute, and equally strong on both sides. The striking feature was an intense cyanosis of the head, neck, arms, and the trunk as far down as the third rib. At this level the cyanosis disappeared with a well-defined line of demarcation, below which the skin was normal in color. Examination of the chest revealed an aneurysm extending from the region of the second to the fourth right intercostal spaces. The sudden collapse and peculiarly localized cyanosis led to the suspicion of a rupture of the sac into the superior vena cava. The death of the patient four hours after admission to the hospital and the subsequent autopsy confirmed this suspicion. The heart was hypertrophied; the aorta was atheromatous; there was a fusiform aneurysm of the descending arch, and a large sacculated one of the ascending and transverse portions; the superior vena cava was flattened over the surface of the tumor, and a tear was found near the opening of the right innominate vein connecting with the cavity of the aneurysm. These findings fully explained the peculiar and unusual clinical picture, and accounted for the localized cyanosis.

A Significant Contribution to the Study of Cancer.

In the present issue of the Medical Record, Dr. Hodenpyl makes the first announcement of certain new principles and methods in the treatment of carcinoma. While various unauthorized statements of this discovery have appeared in the daily press, little which is definite has been heretofore made known. The concise, reserved, scientific treatment which Dr. Hodenpyl now makes puts forth no present claim for a cancer cure, but reveals what seems to be a remarkable biological phenomenon and contains suggestions of a promise of far-reaching benefit to the victims of this sinister disease. It would be rash and unscientific to claim more for this discovery than the author himself claims in his modest presentation of the subject, but it is permissible to welcome it as one step forward in the progress toward the solution of a problem which is engrossing the attention of a multitude of workers the world over and which no one who is conversant with the work of these investigators can doubt will finally be solved.

News of the Week.

The Association of Tuberculosis Clinics of the City of New York was incorporated recently. Its purpose is to organize dispensary control of tuberculosis in New York and develop a uniform system of operation of such dispensaries as are organized. The association will retain patients under observation until they are satisfactorily disposed of and prevent them from drifting from one dispensary to another. It will facilitate the work of visiting nurses in the homes of the patients and provide, where necessary, special funds and assistance for the patients, such as proper hospital, sanatorium, or dispensary care. It will cooperate with the Board of Health in the suppression and cure of tuberculosis. The incorporators are Dr. James Alexander Miller, Dr. John H. Huddleston, Dr. John S. Billings, Jr., Dr. Gaylord S. White, and Mr. Lawrence Veiller of No. 105 East Twenty-second street.

A Medical Tribunal Suggested.—At a dinner tendered to Dr. Carlos Frederick McDonald recently in New York, ex-District Attorney William Travers Jerome in a speech warmly advocated the formation of a tribunal in the medical profession, with powers similar to the Appellate Division of the Supreme Court over lawyers, to disbar or suspend unworthy members of the medical profession. In reference to the subject of expert testimony Mr. Jerome spoke as follows, as reported in the *New York Times:* "There is no subject on which more poll-parrot nonsense is uttered than the subject of medical expert testimony. Out of the fifteen thousand lawyers in New York there are not more than fifty who are qualified by experience to speak with authority on this question. No man has had more experience with experts than myself during the eight years I was District Attorney. And during that time I recall only one man whose testimony was radically dishonest. There were many who disagreed with me honestly. In only one case was there any miscarriage of justice. And in every case the judgment of the experts retained by the State was justified by subsequent clinical history. There was only one case which attracted great public attention, and there was only one physician who was touched by the great scandals arising therefrom. And I am positive in stating that the scandals arose through judicial incompetency rather than from any corrupt medical testimony."

To Amend the Insanity Law.—Assemblyman J. S. Phillips has introduced into the New York Assembly, at Albany, two proposed amendments to the Code of Civil Procedure and the insanity law which are aimed to meet the situation involved in such repeated attempts to secure freedom from asylums as have been made by Harry K. Thaw and others. Under the present procedure there is no limit to the number of attempts which may be made through certiorari and habeas corpus writs to secure the release of such persons. The first of the Phillips bills would amend Section 2016 of the civil code by providing that except as provided in Section 93A of the insanity law a person shall not be entitled to a writ of certiorari or of habeas corpus when he has been committed to or is detained in a State hospital for the insane or for insane criminals or for insane convicts by virtue of a judicial determination of his insanity by a competent tribunal and has been granted one writ. The second bill provides Section 93A as a new section of the insanity law and limits the right of a person confined in a State hospital to a second writ of habeas corpus or certiorari. It requires a certificate under oath of two physicians that they have examined the person under custody and believe him to have recovered his sanity. The authorities of the hospital may present facts in opposition and the granting of the writ is within the discretion of the Court.

Pure Polonium is reported to have been isolated by Mme. Curie of the Paris Sorbonne, the discoverer of radium. It is stated in the dispatches that polonium has a radioactivity 400 times more powerful than radium, but that its active life is much shorter.

New York State Health Commissioner's Report.—In this report of Dr. E. H. Porter to Governor Hughes he lays stress upon the pollution of State waters. He says in part: "Many of our streams have reached the limit of the amount of pollution they will care for. That such a condition

of affairs exists is a disgrace. Little relief in the conditions can be obtained under the existing laws, and the Legislature is urged to pass a bill affording effective means for requiring the pollution to be taken out of the streams. In many places where the water supplies are protected by rules of the department, orders have been issued to clean up the watershed. Particular attention has been paid during the year to summer resorts having impure water supplies and improper methods of sewage disposal. The conditions of a number of places have been found to be dangerous to the persons visiting them, and the Commissioner insists that they be placed in proper sanitary condition."

Pasteur Institute for Toronto.—Several physicians representing the Toronto Academy of Medicine waited on the Cabinet of the Ontario Legislature, on February 14, and requested that a Pasteur Institute be established in Toronto, in connection with the University. The deputation was composed of Prof. McKenzie of Toronto University, Dr. R. A. Reeve, Dr. Alex. McPhedran, and other prominent practitioners of the city. In view of the fact that there is quite a "mad dog scare" in the western part of Ontario at the present time, and that many victims of dog bites have gone to the Pasteur Institute in New York for treatment, the physicians of Toronto contend that such an institute should be established in connection with the University there.

To Abolish Compulsory Vaccination in Ontario.—A bill was introduced into the Ontario Legislature, on February 11, which seeks to abolish compulsory vaccination. Municipal councils now have the right to pass by-laws to enforce compulsory vaccination. Some councils have availed themselves of these powers. The bill is to repeal the present act and to leave it to each person to decide for himself whether or not he shall be vaccinated.

Optometrist Bill in Massachusetts.—A bill is now before the Massachusetts State Legislature, which, if passed, will license optometrists in that State in a somewhat similar manner to the existing law in New York State.

Army Medical Supplies Bill.—A deficiency appropriation of $307,000 to replace medical and hospital supplies destroyed by fire at the army medical supply depot in New York City on February 4 last was recommended to Congress recently by Secretary of War Dickinson. The recommendation is based on a report by the Surgeon-General of the army that the balance of the appropriation for this year is insufficient to meet this extraordinary loss "without dangerously encroaching on the reserves which every provident Government must maintain in anticipation of military emergences such as the recent intervention in Cuba requiring the immediate issue of large quantities of equipment."

Virginia Epileptic Colony.—Within the last few days, Virginia has selected an admirable site on which to locate an Epileptic Colony, as provided by the Legislature. The place, which has been purchased for $35,000, is located within two miles of Lynchburg, but is secluded. It is in the foothills of the Blue Ridge and has a frontage of three miles on the James River, and contains 1,000 acres of well watered and wooded land, about one-half of which is either rich lowland or fertile, tillable soil. There are several houses on the place which may be used for various purposes in starting the colony.

La Crosse Asylum to Be Rebuilt.—The Wisconsin State Board of Control has notified the county board that the La Crosse insane asylum at West Salem is to be reconstructed at a cost of $60,000.

A New Contagious Disease Hospital in New York Harbor.—Health Officer Doty expects to have completed and ready for occupancy on Hoffman Island, in New York Harbor, on March 1, a hospital and four pavilions for the isolation and treatment of measles, scarlet fever, and diphtheria. Previously such cases have been allowed to go on with the ship to its pier, and at the pier have been turned over to the Board of Health. Dr. Doty believes that the removal of those patients at quarantine furnishes better protection to the public than the older method of supervision. Dr. Doty's opportunity to carry out his ideas in the matter was given him by the transfer on June 1, 1909, of the duties of the Quarantine Commission to the Health Officer of the Port, with full jurisdiction over Swinburne and Hoffman Islands. With the approval of the Governor and of the Legislature Dr. Doty has reconstructed a large dormitory in the northern end of Hoffman Island into a hospital and has added to this four wooden pavilions. The five buildings will accommodate 300 patients. The various sections are separated for the most part by glass partitions. The Health Officer is making arrangements to give local health officers and other physicians opportunity to study at first hand the methods of his staff in the treatment of the various infectious diseases. These students of the problem will be put up at Hoffman Island for a few days each without expense to them. The total cost of the hospital and pavilions, including an estimate of the original cost of the old dormitory, is something less than $230 a bed.

Typhoid Fever on Washington Heights.—A small but rather sharp epidemic of typhoid fever has recently made its appearance in the Washington Heights section of New York City. The epidemic is strictly localized in this neighborhood and Commissioner Lederle is reported to have stated that its source had been discovered and eliminated.

Scarlet Fever in New York.—Scarlet fever seems to be decidedly more prevalent in New York this winter than usual. For the week ending February 12, 632 new cases of the disease were reported to the Board of Health as comparing with 339 for the corresponding week in 1909. The disease is most prevalent in the lower east side of Manhattan and the Brownsville section of Brooklyn. There are said to be about 2,500 cases in Greater New York.

New Jersey State Board to Investigate Cold Storage.—The New Jersey State Board of Health has decided to institute an investigation into the condition of the cold storage plants in that State. The inquiry will be conducted under the supervision of Dr. R. B. Fitz Randolph, who has charge of the State Laboratory of Hygiene. Samples of meat, poultry, eggs, and other cold storage stuff will be subjected to analyses. Should these disclose any violation of law the Attorney-General will be asked to prosecute.

A Pension Asked for Yellow Fever Victim.—Application for a pension of $100 a month has been made by John B. Kissinger of South Bend, Ind., on the ground that he offered himself for inoculation with yellow fever during the Government experi-

ments in Havana a few years ago, that he contracted the disease, and has never recovered his health.

"Typhoid Mary" Released.—The woman who a few years ago was the cause of a series of local epidemics of typhoid fever, and gave the original clew to the possibility of healthy persons being "typhoid carriers," with the result that she has been quarantined for three years on North Brother's Island in New York, has finally been released by the Board of Health on the condition that she will not return to her former occupation of a cook and will report to the Board of Health at frequent intervals.

The German Roentgen Society will hold its Sixth Congress in Berlin, beginning on April 3, 1910, at the Langenbeckhaus. Lectures and demonstrations should be announced to the secretary of the society, Dr. Immelmann, Berlin. W. 35, Lützowstrasse 72, before March 4, 1910.

The Medical Society of the Missouri Valley will hold its twenty-second semiannual meeting at Omaha, March 17 and 18, 1910, under the presidency of Dr. A. B. Somers. The arrangements are under the auspices of the Omaha-Douglas County Medical Society. Members of the association desiring to present papers at this meeting should send their titles to the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo., at once. Abstracts of papers must be furnished by February 20, to insure a place on the program.

Dr. Jacobi's Text Book.—In the review of the "Collectanea Jacobii" (MEDICAL RECORD, February 12, 1910) an error was made by using the expression "Though he has written no text books." The mistake was made by the reviewer in misinterpreting the words of the editor of the "Collectanea Jacobii," who in his preface said "he has not rehashed any text-books and then published them as his own." The last edition of Dr. Jacobi's "Therapeutics of Infancy and Childhood" was published in 1903 by the J. B. Lippincott Company.

University Appointments.—Dr. George W. Vandegrift of New York has been appointed Professor of Ophthalmology at the Brooklyn Post-Graduate Medical School and Attending Ophthalmic Surgeon to the Williamsburg Hospital, Brooklyn. Dr. Mary M. Wolfe has been appointed Clinical Professor of Psychiatry in the Woman's Medical College of Pennsylvania.

The Late Dr. Follen Cabot.—At a meeting of the Faculty of the New York Post-Graduate Medical School, on February 14, the following resolutions were adopted: *Whereas:* We learn with profound sorrow of the sudden and untimely death of our esteemed associate, Dr. Follen Cabot, Jr., who has been connected with this School for the past twelve years, and has held the Chair of Professor of Genitourinary Diseases in this Faculty since 1907, and *Whereas:* It is but a just tribute to his memory to say in deploring his removal from our midst, that we mourn for a man whose integrity and character were above reproach, who was faithful to his trust, and who always gave his best for the advancemet of his specialty in this School, and *Whereas:* It is particularly to be regretted that he should have been cut off from his life work at so early an age, and as a result of his hard work and conscientious devotion to his duty, much of which was in the interests of this School, therefore, be it *Resolved:* That we hereby record a last sad tribute to his memory, and unite in expressing our heartfelt sympathy to his sorrowing and bereaved widow and children, and be it further *Resolved:* That these preambles and resolutions be spread upon the minutes of this Faculty, and that a copy of the same be transmitted to his widow as a token of our respect, and as reverence to his memory. EUGENE FULLER, M.D., GEORGE G. WARD, JR., M.D., *Committee.*

Obituary Notes.—Dr. JOHN E. JAMES of Philadelphia died suddenly on February 16, 1910, aged 66 years. He was a graduate of the Medical Department of the University of Pennsylvania in 1866 and of the Hahnemann Medical College in 1886, in which institutions he was Professor of Gynecology.

DR. CHARLES F. MCGAHAN of Aiken, S. C., died at his home February 15, 1910, aged 49 years. He was a graduate of the Dartmouth Medical College in 1885, and a member of the Aiken County Medical Society, the South Carolina Medical Association, and the American Medical Association.

Dr. FREDERICK WENTWORTH MERCER of Chicago died at his home on February 9, 1910, aged 71 years. He was a graduate of the College of Physicians and Surgeons of New York in 1862, a surgeon major in the Civil War, and a member of the Chicago Medical Society, the Illinois State Medical Society, and the American Medical Association.

Correspondence.

PROFESSOR POLITZER TO HIS AMERICAN PUPILS AND FRIENDS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In reference to the anniversary of attainment of the degree of Doctor of Medicine at the University of Vienna my American pupils and friends have given so many evidences of friendship and attachment, that I am only able in this way to thank them all. I beg to say to all American specialists who visit Vienna, if they will call on me it will be a source of great pleasure to show them my collection of pathological and anatomical specimens which, through years of careful selection, contains many instructive objects.

At the same time, I would like to inform those colleagues who are under the impression that I have retired from private practice, that such is not the case, and that I am carrying on my consultations and practice now just as I did formerly.

Thanking you in advance for your kindness in publishing this letter, I beg to remain, faithfully yours,

PROF. DR. A. POLITZER.

VIENNA, January 30, 1910.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

VENTILATION OF SCHOOLS—BACTERIA IN LOW TEMPERATURES—SPINAL ACCESSORY NERVE—SPLENIC ANEMIA—FIBROLYSIN—OBITUARY.

LONDON, February 4, 1910.

THE school medical inspectors have evidently paid great attention to the subject of ventilation. Dr. Newman, chief of the department, in his report noticed in my letter of the 21st, ult., refers to the cases in which defects have been reported. These defects he attributes to (a) inadequate or defective means, or (b) full advantage not being taken of the means that exist. As a rule, natural methods are depended on, *e.g.* windows, doors, open fireplaces, and these are supplemented by Tobin's tubes, Boyle's valves, Sheringham valves, Galton's grates, roof, ridge, or ceiling ventilators, air gratings, and towered openings. Where inadequacy was recorded an increase in the number or area of windows, or some auxiliary means, were suggested. In some cases inadequacy was only relative, due to overcrowding. In some cases the ventilators were out of order or improperly situated. In others

the defects were of a radical kind. It is evident from many reports that the teachers do not make adequate use of the means at their disposal. In many schools the windows were not sufficiently opened and there seemed to be no attempt to secure cross-ventilation. These school medical officers made analyses of the air in schools and give tables of the results. Dr. Oliver found in the various rooms of one school from 8 to 21 parts per 10,000 of CO_2, instead of the fresh air standard of 4. Dr. Clements found in two schools 9 to 15. Dr. Williams in three schools found from 6.8 to 11.8. These proportions prove the need of teachers being intrusted to make use of all the means at their disposal to secure fresh air in their schools.

Sir James Dewar, lecturing last week at the Royal Institution, said he had been trying to press further our knowledge of what actually takes place when micro-organisms are subjected to very low temperatures. At the time liquid air was produced it was shown that the germs of putrefactive organisms in the air were still active. When liquid hydrogen was made, seeds from Kew were kept from 6 to 7 hours under the hydrogen without killing them. The tubercle bacillus subjected to the same treatment suffered no modification of its virulence. The phosphorescent bacteria, said Sir James, were good subjects for investigation, for as long as they were living they were luminous and their luminosity was essentially connected with their vital transformation. Therefore, it was easy to observe when death had taken place, so it occurred to him that experiments might be arranged to determine whether any known agents produced any effect on these bacteria at excessively low temperatures. Here he propounded some experiments before the audience. In one he showed a metal plate covered with bacteria which were luminous in the dark. A quantity of liquid air, which the lecturer declared to be less dangerous than had been supposed was then poured over the plate, when the luminosity vanished. Next by moving the plate to and fro, so as to raise the temperature, the phosphorescent bacteria again became visible. "You cool them, but you do not kill them," said Sir James, and continued that there was no getting over the fact that chemical action takes place at low temperatures and there would be nothing extraordinary in admitting that a solid piece of protoplasm might in certain cases be capable of being broken up in such a way that it was not a living organism.

At the Medical Society of London, on the 24th ult., Dr. Parkes Weber showed a case of frequent attacks of vomiting, tympanites, and abdominal pain. The patient, a woman of 36, had suffered for some 14 years, during which she had been at times in several hospitals and had had the abdomen opened four times, but no organic disease had been discovered. The case had been described in the *Transactions* of the Society for 1898 and a further history given in *Brain*, for 1904.

In 1896-1897 there had been vomiting of feces, having the form of scybala and of enamata of oil and others colored with methylene blue. Dr. Guthrie discussed the case in reference to enterospasm. Mr. Barker referred to another similar case in which he had conjectured a communication between stomach or colon. Mr. Openshaw said he had operated on a case diagnosed as reflex peristalsis. A distinct lump was felt along the greater curvature. At the operation he found a communication between the stomach and the colon. In his reply Dr. Weber pointed out the significance in such a case of the formed scybala.

Mr. Warren Low showed a case operated on 18 months previously for removal of a carcinoma of the pelvic colon. End-to-end anastomosis of the bowel was done and there is no inconvenient result. Mr. Low examined him a week ago and found no sign of recurrence. The sigmoidoscope passed easily for 8 inches and the lumen of the bowel when inflated could be inspected further on. Dr. Spilsbury examined the growth and reported it to be an adenocarcinoma projecting into the lumen as a polypoid. The peritoneum at the back of the growth was puckered but not invaded. There was marked muscular hypertrophy of the bowel.

Mr. Openshaw showed a case of paralysis of the spinal accessory nerve after a removal of the cervical glands. The whole of the trapezii and the left sterno-mastoid muscles were atrophic, but the right sterno-mastoid acted feebly. In such cases Mr. Openshaw said the spinal accessory should certainly be sutured if it had been divided, and Mr. Drew urged the importance of separating the nerve when removing the glands. Dr. W. Harris remarked on the very slight disability produced in these cases. The patients could do almost anything except carry weights on their shoulders.

In the previous meeting of the same society, there were several interesting exhibits, among which Dr. P. Weber showed a heart affected with chronic malignant endocarditis from a case which he said had simulated splenic anemia. The patient had been a sailor who contracted malaria when abroad and developed an enlarged spleen. He had been in several hospitals and the diagnosis in each had been splenic anemia. Dr. de H. Hall remarked on this that a good deal of doubt existed as to "so-called" splenic anemia, a disease which was not based on satisfactory evidence, so that its diagnosis suggested sceptiasm. Dr. Parkinson mentioned a case of malignant endocarditis in which during life the spleen was observed to be enlarged, and Dr. S. West said there was a further difficulty to be considered, viz., that malignant endocarditis might be a secondary infection.

In the Clinical Section of the R. S. M., Dr. Howard showed a case of stricture of the rectum and recto-vaginal fistula. The condition had followed an operation for hemorrhoids at a hospital. Colotomy had been proposed, but the patient (a woman of 40) refused to submit to it. In June, 1900, injections of fibrolysin were begun, the condition at that time being very distressing. The finger could not pass through the stricture without an anesthetic and the feces were passed as much by one passage as the other. At the time of the meeting (January 14) the following improvements were stated to have taken place: (1) An arrest of the growth of the fibrous tissue; (2) a certain amount of absorption of the stricture; (3) relief of pain; (4) the motions were passed, per anus, with little or no pain. The fistula was reduced to a small slit, though it was not presumed that this was an effect of the fibrolysin. The President, Mr. Pearce Gould, confirmed the statement that the stricture at this time was patent.

Dr. Leonard Williams related a case of sciatica treated by fibrolysin injections over the nerve, which seemed beneficial, as in three weeks the patient walked well.

Prof. Osler asked if any member had tried fibrolysin in Dupuytren's contraction, to which Mr. Carless replied that he had given iodolysin for it by the mouth and after six months the fingers were more movable.

Mr. Tilley remarked that as to ear cases reported the scars said to have been improved were out of sight.

Mr. Barker had seen no advantage from fibrolysin, but some disadvantages. In one case of Volkmann's contraction sloughs had followed. Sciatica might be benefited by the mere meddling. He could not see how Dupuytren's contraction could be remedied by the injections which could not affect any absorption of fat.

Two deaths have to be reported in connection with the Royal London Ophthalmic Hospital. Mr. William Ilbert Hancock, F.R.C.S., assistant surgeon, died on the 26th ult., aged only 36, but he had attained a good reputation in his specialty, to which he had made some useful contributions, chiefly in the *Transactions* of the Ophthalmological Society. His colleague whose death has also occurred, Dr. Daniel Mowat, was an Edinboro graduate, M.B., C.M., 1884, and M.D., with honors, 1887. He will be remembered by many of our readers who have been over here, for he was the Chief Clinical Assistant at the hospital, a post in which he diligently worked for 22 years. He contributed to the society and *Transactions*. His most important paper, perhaps, being on "Lymphangiectasis of the Eyelids."

Lt.-Col. C. M. Douglas, V.C., M.D., died on December 31 last, aged 69. He entered the Army Medical Service in 1862 and retired in 1882. He was awarded the Victoria Cross early in his career for the "gallant and daring manner" in which he and four privates of his regiment risked their lives and thereby saved seventeen officers and men from fearful risk, if not certainty of death.

Dr. J. N. Prentice died suddenly on January 24, at Ladybank, Fifeshire, where he had practised for four or five years. He was only 32, and was visiting patients within three days of his death.

Dr. Evan Thomas died on January 15 from septicemia contracted while making a post mortem a few days previously. He was M.D. and B.S. Lond.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

EPIDEMIC OF TYPHOID FEVER IN MONTREAL—OUTBREAK OF TYPHOID FEVER IN TORONTO—RABIES WIDESPREAD IN PROVINCE OF ONTARIO—FOOD SUPPLY AND COLD STORAGE IN CANADA—VITAL STATISTICS OF ONTARIO—MEDICAL STUDENTS IN UNIVERSITY OF TORONTO—THE ANNUAL MEETING OF THE CANADIAN MEDICAL ASSOCIATION—ENLARGING ST. MICHAEL'S HOSPITAL, TORONTO—CONSERVATION AND PUBLIC HEALTH IN THE DOMINION OF CANADA—ADDITION TO ISOLATION HOSPITAL IN TORONTO—DEATH OF DR. JAMES H. RICHARDSON.

TORONTO, February 9, 1910.

THE most serious happening in Canada from a medical and a sanitary standpoint has been the outbreak of typhoid fever in Montreal. It is believed now that the epidemic, for it has been no less, is subsiding, but data concerning the outbreak is very difficult to come at. Unless one is on the spot, even now it is by no means easy to discover whether the number of cases are really becoming fewer, or whether the whole matter is being concealed so far as is possible from the outside public. It was announced, it is to be presumed officially, as the announcement is published from the *Canada Lancet* for February, that there were 226 fresh cases in the city of Montreal in the last week of December, and that the deaths from the disease during the same period numbered thirteen. It is obvious that matters in the early part of January had not bettered greatly, because it was found absolutely necessary to establish an emergency hospital, the other hospitals being filled to overflowing. The history of the emergency hospital is interesting. It appears that the city fathers of Montreal were not impressed with the need of providing further accommodation for typhoid patients, or at least that they were not willing to vote the money requisite for the establishment of an emergency hospital. This being so, some public-spirited citizens of Montreal decided to take the bull by the horns and supply accommodation, treatment, and nursing for typhoid fever patients. Four days after this resolution had been come to a fully equipped hospital with an adequate and competent medical and nursing staff had been organized, and an ample guarantee fund subscribed. The old factory building belonging to the Northern Electric Company, capable of accommodating more than 300 patients was let, and, as said before, ready within four days for the reception of patients. There are, however, several points in connection with the epidemic which should be made clear, the most important of which is the cause of the outbreak. Unbiased authorities say that the prevalence of typhoid fever in Montreal is undoubtedly due to a polluted water supply, and Dr. LaChapelle, the chairman of the Quebec Provincial Board of Health, is publicly quoted as saying that in his opinion the contaminated water supply is mainly responsible; and that this condition of things will continue until steps have been taken to render the supply free from disease germs. If this be the case, it would seem to be the duty of, as well as good policy on the part of the city authorities, to recognize these facts and to improve the water supply with a speed. The initial cost may be heavy, but in the long run it will be money well spent.

In Toronto also there are many cases of typhoid fever, far more cases than usual at this season of the year. During January, sixty-one cases were reported to Dr. Sheard, City Medical Officer of Health, and nineteen deaths. Up to the time of writing in this month forty cases or thereabouts have been reported. In January, 1909, only four cases were reported, and in February, 1909, ten cases. Dr. Sheard holds the view that there will be a large increase of the disease in the spring, and furthermore states that winter and spring typhoid in Toronto is wholly waterborne. The malady is of a virulent type, hemorrhage occurring in a larger percentage of cases than usual. Toronto has decided to dispose of the city sewage in a more sanitary manner than that in use at the present time, and has likewise resolved to filter the water supply. Perhaps it might not be going too far to say that Montreal would be wise to follow so rational an example.

A somewhat extraordinary object lesson in the origin and spread of rabies is now being provided in the Province of Ontario. It is said, and there appears to be no doubt as to the truth of the statement, that the disease was first introduced into the Province by a dog which crossed the suspension bridge over the Niagara river at Queenstown in May, 1907. This infected animal bit several Canadian dogs, since which time cases of rabies, or rather it should be said suspected rabies, have cropped up at intervals in different parts of western Ontario. The statement was issued the other day from the Veterinary Director General's Department in Ottawa, that there are probably between three and four hundred mad dogs roaming about all parts of western Ontario. Since May, 1907, forty-two persons, of whom half were children, have been bitten by mad dogs; sixty-three cattle, one horse, six sheep, and thirty swine have died from rabies, and 206 premises have been quarantined owing to the presence of the disease. No deaths among the human beings bitten have occurred. Most of the injured persons went to the Pasteur Institute in New York for treatment.

The situation is considered so grave that the Dominion Minister of Agriculture and Dr. Rutherford, the Veterinary Director General, acting in concert with the Health Department of Ontario have determined to adopt drastic measures to stamp out the disease. Under authority of an order in Council containing regulations in respect to rabies, an order was issued on February 5 by the Department of Agriculture on the report of Dr. Rutherford to the effect that rabies is known to exist in many widely separated parts of the western peninsula of Ontario, directing that all dogs in that part of the Province must either be constantly muzzled, securely chained, or kept under lock and key. The course of the Government of the Province of Ontario has been determined by a similar provincial order in Council drawn up by the Provincial Board of Health. Your correspondent thinking that the situation might be exaggerated, and desirous of obtaining facts from the fountain head, interviewed Dr. Charles A. Hodgetts, secretary of the Provincial Board of Health, on the subject. Dr. Hodgetts most courteously gave him all the information required, and stated emphatically that there was no exaggeration whatsoever; that in the Veterinary General's Department in Ottawa the disease had been demonstrated as rabies in many instances by the inoculation of guinea pigs with virus drawn from suspected animals. In this connection it is instructive to refer to the experience of Great Britain with rabies. But a few years ago the disease was fairly common there, and has been wholly extirpated by muzzling dogs and by quarantining against the importation of foreign dogs. So successful have these measures been, that no muzzling is needed now, for the disease is practically extinct. The Federal authorities of Canada and the Government of Ontario are to be highly commended for running counter to public sentiment in the interests of the health of the community.

As in the States, so in Canada the question of the food supply from the economic and health points of view is being widely discussed. The Hon. S. P. Fisher, Minister of Agriculture, has ordered an investigation into alleged abnormal increase to consumers during past years of the prices of various food products. Also, the manner in which big packing firms make use of, or perhaps it might be said, abuse cold storage plants, is attracting attention. It is alleged that food products are kept back by large packing firms in order to keep up prices. There is another and a more sinister aspect of cold storage which has not been dealt with as its importance deserves. This is the possible or probable menace to health in the abuse of the cold storage system. It is acknowledged that cold storage exerts little or no deleterious influence on food products if employed for a certain number of days only. Several weeks of cold storage may not appreciably harm meat, for instance, although this is doubtful. After a limited time the assertion may be made that deterioration commences and progresses with more or less rapidity, until it reaches the stage when the food becomes a source of danger to health and life. This is a matter which calls for a careful scientific investigation, as it closely concerns the health of the community and of the individual who may have to suffer both in pocket and stomach in order that corporations already over-rich may amass more money.

Vital statistics of Ontario show that during 1908 tuberculosis in all forms caused the death of 2,530 persons, pneumonia killed 2,564, and typhoid fever 500. Pneumonia is about the most deadly disease in Canada, just as it is in the Eastern States of America. The too numerous deaths from this disease may be partly attributed to the sudden climatic variations, but they are more frequently owing to overheated and badly ventilated houses.

Medical students in the University of Toronto number 681, and the cost of the administration of the medical department is stated to be $153,050.

The annual meeting of the Canadian Medical Association will take place in Toronto on June 1, 2, 3, and 4 next. Names of papers must be submitted by February 1, and a synopsis of each paper by April 15. St. Michael's Hospital, Toronto, is to expend forthwith the sum of $180,-

000 on the erection of a four-story addition. Canada wisely intends to profit by the mistakes of some other countries, including the United States, and take time by the forelock in conserving her natural resources. A commission has been appointed recently for this purpose, and it has been announced that questions of public health will come directly within the scope of its work. For example, the Hon. Clifford Sefton, its president, pointed out in his inaugural address that while the Dominion spends annually hundreds of thousands of dollars to eradicate the diseases of animals, nothing is spent to stamp out diseases of men. He thinks that the Dominion will willingly find money to investigate and endeavor to extirpate such diseases as tuberculosis or cancer. The pollution of waters which is manifestly a public health question, will receive the immediate attention of the commission. A new wing is to be added to the Toronto Isolation Hospital at the cost of $102,000. The wing will accommodate 100 patients.

In the account of the death of Dr. James H. Richardson which appeared in the MEDICAL RECORD, January 29, no mention is made of an occurrence in his career that made him better known to the people of Canada than any of his medical achievements. Throughout the length and breadth of the Dominion he was famed as the man who chose the maple leaf as the national emblem of Canada.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 10, 1910.

Suggestion: the Mainspring of Hypnotism and Psychotherapy.—J. S. Lewis says that the average physician may employ suggestion at its full value without charlatanism, without mysticism, without deception, in common-sense suggestive treatment. The patient who leaves the hospital with the delusion that he has been drugged to sleep by virtue of a capsule containing powdered sugar is in no sense better off than the one who leaves with a discharging sinus or a crutch. It should be our endeavor to supplant the bread pill, the bluff wafer, and the sterile water hypodermic injection by verbal suggestion, or, if time be lacking, use these helps only until such time as we can tactfully give to the patient the key to his functional disorder. We can use these means to distinguish between what is functional and what is organic. But once the condition is clear the patient should be given the use of that power with which suggestion has invested the bread pill or the water "hypo." For the competent there is still hypnotism, where the weaker suggestion fails. Is it in vain to hope that this generation shall see many hypnotists in this country, who, like anesthetists, devote their time to this specialty and in particular to the difficult cases? There is need of men who can write and talk intelligently to their colleagues. Most of us fail to sympathize with the possibly honest though flatulent writings of certain professional hypnotists to whom, with averted faces, yet with the hope of cure, we refer our own wrecks of the drink and drug habits.

Prevention and Inhibition of Peritonitis, with Especial Reference to the Harm Done by Cathartics in Incipient Peritonitis.—This subject is considered by A. J. Ochsner, who lays down, among others, the following definite directions: While careful examination should always be made in any abdominal case, violent manipulations are unnecessary. Patients suffering from intestinal obstruction due to either strangulated hernia, constriction by bands or adhesions, volvulus, intussusception, kinking of the gut, gallstones, carcinoma, Meckel's diverticulum, etc., should be operated on at once and should never under any circumstances receive cathartics or food by mouth after any of the foregoing conditions are even suspected. Gastric lavage should be performed in these cases at once and again immediately before operation, and it is well to leave the stomach tube to drain out any intestinal fluid which may regurgitate during operation. Opium should never be given before a diagnosis is made and never in the presence of any form of peritonitis unless gastric lavage has been made and the introduction of every form of food and cathartics has been forbidden. This applies to broths, champagne, and other stimulants. Gastric lavage should be performed in every case suffering from any form of peritonitis except from stomach or duodenal perforation. Water by mouth should not be given in peritonitis until the patient is well on the way to recovery. Instillation of normal saline into the rectum by the drop method of Murphy is one of the most valuable means of inhibiting peritonitis. Large enemata except by the drop method should never be given in peritonitis. In acute appendicitis the organ should be removed before the infection extends beyond it. In acute cases which have received some form of food or cathartics after the beginning of the attack and reach the surgeon too late for a safe early operation and are suffering from beginning diffuse peritonitis, gastric lavage, absolute abstinence from food and cathartics by mouth and the slow instillation of normal saline by rectum are indicated.

New York Medical Journal, February 12, 1910.

Affections of the Colon.—In the course of a general paper on this subject E. Martin says that the large bowel is commonly regarded as an organ the main function of which is to accumulate the feces until such time as their extrusion from the body suit the convenience or pleasure. In health there is but little water extracted from the feces by the intestine. The bacterial content is much larger then than that of any other part of the intestinal tract. He alludes to the common affections of the tract and deals with the dangers which may follow absorption of its contents. Muscular atony, torpor, and enteroptosis are complications which may follow exhausting diseases. As to the effect on developed enteroptosis of any belt or support, *x*-ray examination seems to show that there is practically none. Relief to symptoms may come through these measures. The author is inclined to give a support to the theories of Metchnikoff, though it is difficult to form a clear judgment as to the value his measures may have in preventing intestinal putrefaction. The question as to whether surgery is called for in large intestinal conditions depends on the possibility or not of efficient colonic irrigations. If they can be given there would seem to be no call for appendicostomy or colostomy. He calls attention to cases described by Lane in which the intestinal stasis is due to gut fixation dependent upon bands passing from the parietal peritoneum and producing such functional results that the large intestine becomes a foul, undrained, and undrainable sewer. Lane's picture of the toxemia resulting from this condition is extremely vivid. Other symptoms on which a definite diagnosis might be based are not given in detail. His treatment consists in an ileosigmoidostomy either with or without complete removal of the colon, the more radical operation being indicated in the cases characterized by pain. He has thus operated upon many patients, but gives neither the total number nor information concerning the perseverance and skill with which a previous unavailing hygienic, medical, and mechanical treatment was applied; nor are ultimate results noted. Under such circumstances his contribution, though full of promise, will probably remain for most surgeons a matter of curious speculation until further experience, which, it is to be hoped, may be gained at the expense of other than American citizens, will have demonstrated the applicability and utility of his procedures.

The Medical Aspect of Affections of the Colon.—L. Weber speaks of acute infection and disease and of chronic infection. Under the first head he includes dysentery, diphtheritic inflammation of the ileocolon in the course of acute infectious diseases, or as a terminal process in chronic disease, or through mercurial and other metallic poisons, and ileocolitis. He looks on mucous colitis as a neurosis. Of chronic cases of ileocolitis—catarrh without infiltration or with hypertrophy or atony of alternate portions of the colon which do not offer the signs of ulceration—there have been many cases reported which have not yielded to careful dietary, or irrigations per rectum in connection with the albuminate tannic acid by the mouth in 15-grain doses five times daily. Here the most careful examination of the stools for mucus, shreds of mucosa, parasites, and particles of organized material indicating new growth is of the utmost importance. He has had two cases of ileocecal tumefaction which with the greatest probability could be diagnosed as tuberculous. He closes with the relation of three interesting cases, one of hepatic abscess of the left lobe occurring ten years or longer after dysentery, in which the patient might have been saved by timely operation, which terminated fatally by perforation into the right pleural cavity; another showing that the entire colon may be filled with feces for two years and return to a normal condition after operation, and a third proving that even a very aged person who is still alive can get along without a colon for nearly three years and main-

tain her health and weight. The stools she passes prove good digestion. A permanent artificial anus was established in the cecum.

The Problems in a Case of Typhoid and Pregnancy.—S. M. Brickner and B. S. Oppenheimer relate a case of this nature in which with the exception of typhoid the pregnancy followed a normal course. The patient was placed on a Prochownik diet and had a premature labor at the eighth month, a dry labor requiring low forceps for prolonged second stage. Recovery was complete. The authors study the literature of the condition and advance the following statements: Pregnancy certainly does not confer complete immunity against typhoid as was thought years ago. They believe that in typhoid complicating pregnancy up to the fourth month the typhoid will be the predominating factor and the temperature higher than with a later pregnancy, whereas if typhoid occurring after the sixth month, the pregnancy will prevail, so to speak, and the typhoid will be mild. As to the influence of typhoid on pregnancy the latter is terminated in about 65 per cent. of the cases by premature labor or abortion. Transmission by placenta from mother to fetus occurs in various infectious diseases. It probably does in typhoid, but in the fetus in such cases the result to the fetus is almost invariably a pure typhoid sepsis without any lesions in the intestines or mesenteric nodes. As regards placental transmission the Widal test was found positive in the fetus in seven out of twenty-five cases on record. Most authors do not believe in the transmission of agglutins from mother to infant through the nourishment. The Widal reaction was present as early as the sixth day after the patient took to bed. The hematuria which she had was regarded as due to urotropin she had taken. The mother's condition should make the indication for artificial delivery. Forty-four per cent. of the children are saved. Certain authorities have found in the children of mothers who have suffered from typhoid or other infectious diseases during pregnancy show certain abnormalities, anatomical, chemical, and physiological. Thus far the child referred to by the authors has had a normal development in every way.

The Contractile Elements in the Connective Tissue.—J. Wright presents a paper on this subject dwelling on the elastic fiber, its origin, structure, biogenesis, and dynamics. He speaks of the theories of origin, some regarding it as embryonic while others consider it intracellular. In the author's own observations there are appearances in adult tissue which argue for the origin of the elastic fiber from the exoplasm of cells. So far as concerns the modus operandi of elasticity which the author develops from the anatomical account of a granular stage in the genesis, it matters not whether the fiber is built up of visible or invisible granules or whether it is formed within the cell or in the ground substance. Elastin whatever its source is manifestly a living thing. From his own experience the author thinks there can be no doubt that the elastic fiber has the power of reproducing itself by branching or longitudinal fission. The elastic fiber is frequently demonstrable in the stroma of cancer and fibroma. It has been suggested that the fibers have been squeezed out of the cells by the pressure of excessive growth, but the author thinks this is a lame conclusion. In certain chronic inflammations the elastin or stuff taking the Weigert stain is thrown out in abundance. In atrophic processes and in edematous infiltrations supervening on the chronic inflammations both the elastic fiber and unformed elastin finally disappear. In the chronic inflammations referred to as producing elastin apparently as an exudate of connective tissue cells there is always a considerable diminution of efficient elastic fibers. That chromatin can be built up out of elastin is not impossible in view of the fact that after all within the nucleus it is built up out of material in the surrounding protoplasm, perhaps of the elastin itself. It has been held that chromatin, whatever else of a directive and formative nature it may represent, is a reservoir from which energy is radiated to surrounding protoplasm, while elastin in this regard may well be looked upon as a substance of lower potentiality. It is chiefly a matter of degree and complexity. Let it be remembered, however, that elastin does not become elastic until its granules or its molecules are arranged in efficient order.

Journal of the American Medical Association, February 12, 1910.

Amebic Dysentery.—J. M. Anders and W. L. Rodman discuss treatment of amebic dysentery. One of the most important indications is rest, especially in the acute form of the disease, and to insure it in some rare cases opium may be required. So long as scybalous masses are being passed, they prefer to use Epsom salts in dram doses every third hour. If the general strength is good a brief course of calomel should precede the use of the saline. In their opinion purgatives have no place in the advanced stages of amebic dysentery or in the treatment of cases of highly acute invasion symptoms. The saline laxatives, therefore, in all cases should not be long continued after the dysenteric ejections have been made diarrheal. The question as to whether there is a specific remedy for the disease is taken up and the authors have been profoundly impressed with the therapeutic value of ipecac in the early stages of the disease. Its success depends on the method and care of its administration, and with capsules of animal membrane or salol-coated pills large doses can be used without provoking nausea. They advise not less than 30 grains at a single dose on the first day, diminishing the amount 5 grains a day so that on the sixth day only 5 grains are given. They doubt whether the irrigation treatment by rectum has been more successful than the ipecac treatment, but some authorities, like Boggs, claim that the local treatment is the only effective medication. For this purpose quinine solutions are most approved, commencing at 1:5,000 blood-warm solution and progressively increasing in strength to a 1:1,000 in a few days. Most authorities think it wise to begin the irrigations after the acute symptoms have, in part at least, subsided. Next in efficiency to quinine is silver nitrate in solution. Special mention as regards details is made of marked elevation of the hips, the use of a soft rectal tube introduced from 3 to 4 feet into the colon, and the retention of the enema for from 15 to 20 minutes. The irrigations should be kept up until repeated examination shows no amebæ in the stools. Success will depend somewhat on the location of the ulcers. If high up in the bowel they are less easily reached. Two cases are reported in which the operation of appendicostomy was performed to facilitate the complete irrigation of the large bowel with success. They believe in doing the operation in two stages and advise against ligation of the mesoappendix on account of the danger of gangrene. It is especially in cases where the lesions are highly placed in the bowel that this method will be most useful. Cecostomy is mentioned but not considered as advantageous as appendicostomy.

Oral Prophylaxis.—The importance of personal cleanliness of the mouth as a factor in the prevention of disease is emphasized by A. Irwin, who thinks that it is through the public schools that a reform in this matter can be accomplished. The mouth may become the gateway for all kinds of pathogenic germs and, without attention to this, the school may become a menace to the health of the commonwealth. Epidemics may originate from oral infection which could be avoided by due attention to cleanliness. He gives a summary of the work done along this line in various parts of the country and abroad in the inspection of school children's teeth and submits the following propositions for consideration: "1. Oral prophylaxis is the art of preventing disease, deformity, and injury to the mouth by means of manipulation, instrumentation, and skillful surgical treatment. 2. Practical application of oral prophylaxis (prevention by surgical instrumentation) should be made in behalf of public school children. 3. The consent and active cooperation of the school authorities is the most essential consideration now to secure the introduction of oral prophylaxis into the public schools by dentists. 4. The practical application of oral prophylaxis is a problem in economics, because it is the most effective means of combating the spread of contagious disease from oral infection among the public. 5. The solution of the problem lies in the establishment of free dental school clinics for the introduction of oral prophylaxis by dentists."

The National Formulary.—H. P. Hynson relates how the National Formulary originated out of the multiplicity of local formularies that had appeared a little after the middle of the last century, stimulated by the increasing number of "elegant preparations and the then increasing activity of the homeopaths." The idea was to consolidate these local formularies, and it was not the intention of the American Pharmaceutical Association to set up a standard for the medical profession. Since its earlier editions it has served a good

purpose and developed and improved in all regards as rapidly as could be expected. The adoption of an unfortunate plan or policy for the earlier editions may be blamed for most of the bad pharmacy which it contains. When the formulas are constructed to provide for permanent instead of extemporaneous products the poor pharmacy complained of will disappear. The recognition of the National Formulary by the Government has greatly enhanced its importance and has led the American Pharmaceutical Association to undertake a complete and rigid revision, making the coming edition as nearly ethical and scientific as the present-day exigencies of medical practice will permit. Hynson quotes in this connection from the report of the committee on revision as to the policy adopted regarding the admissions and eliminations that are to be made. Just and helpful criticism is requested to aid the work, and the writer says that deserved praise will be appreciated.

Simulated Tubal Pregnancy.—H. S. Crossen says that the difficulties of diagnosis of tubal pregnancy are due largely to the fact that many cases are atypical, presenting some symptoms but not all. These may be grouped in two classes—first, those in which the principal feature is a tender pelvic mass associated with some of the other symptoms, and second, those in which the principal feature is sudden abdominal pain and collapse without apparent cause. First among the first class he mentions gonorrheal salpingitis. Ovarian and broad ligament abscess may also cause confusion and embarrass diagnosis, and three cases of this class, discovered after operation, are reported. There are various anomalous conditions that may cause an intrauterine pregnancy to simulate a tubal pregnancy. He reports cases of hydatiform mole, hysteria with uterine displacement, irregular softening of uterus during pregnancy, and retrolateral and anterolateral flexions which have caused mistakes of diagnosis of this kind. Tumors may produce similar errors. When a married woman in the child-bearing period is seized with severe abdominal pains without apparent cause and passes into collapse such as is usually associated with severe internal hemorrhage, we naturally think of ruptured tubal pregnancy. If there happens to be a history of missed menstruation a tentative diagnosis of rupture and prompt action accordingly is justifiable. Hence the importance of careful consideration of all the causes that may cause such symptoms. Among these are hemorrhage of the ovary, ovarian cyst with rupture, hematosalpinx, salpingitis with collapse, ruptured appendix and pelvic tumor, and fulminating pelvic edema. Summing up, he insists on the importance of excluding sudden exacerbations of dormant gonorrheal salpingitis by careful examination for all possible symptoms of that condition and also the rare cases of acute gonorrhea which manifest themselves by explosive tubal symptoms. An early miscarriage, if associated with tumor or followed by mild salpingitis, may simulate tubal pregnancy. An unsuspected tumor in the pelvis may give rise to severe disturbance and, if other symptoms indicating tubal pregnancy occur, mistake is easily made. Ovarian hemorrhage or tubal hemorrhage may so closely simulate extrauterine pregnancy as to be indistinguishable before operation and in some cases even leave doubt after an operation has been performed. In addition to the affections mentioned salpingitis, appendicitis, and perforations in the gastrointestinal tract, and fulminating pelvic edema are also causes of error at times.

Tetanus Antitoxin.—C. J. Rowan reports a case of tetanus with mixed infection in which the patient received a prophylactic dose of 1,500 units of tetanus antitoxin. Notwithstanding this, tetanus developed on the twenty-fifth day and terminated fatally in four days. While several European cases have been reported of tetanus following prophylactic doses of antitoxin, this is the first one he can find reported in this country. An examination of another 1,500 unit package from the same lot, made by Dr. M. J. Rosenau of the Hygienic Laboratory, Washington, D. C., revealed that it contained over 2,000 units or 500 more than it was claimed to contain. Rowan concludes that, while 1,500 units of antitoxin will prevent tetanus in case of wounds not followed by severe infection, it may fail when used only once when there exists a mixed infection lasting over ten days. In such cases the author would advise a repetition of the dose every week while the infection lasts, especially if the latter is due to any of the saprophytic bacilli, which reduce the resistance to the tetanus bacilli.

The Lancet, February 5, 1910.

Ankylostomiasis a Menace to the Industrial Life of Nontropical Countries.—T. Oliver discusses this question from the standpoint of history as well as from present conditions. Only three factors are necessary for the development of the parasite, oxygen, a favorable temperature, and moisture. It is in badly ventilated and moist coal mines that the best grouping of these conditions favoring development are found and consequently free ventilation is the first thing to be attended to. It has been found that ashes taken from the engine rooms about the mines give, when soaked in water, an alkaline reaction and are hostile to ova and larvæ. If this fact shall prove to be well grounded we have in cinder ash a cheap and effective way of combating the disease in coal mines by filling up the grooves at the sides of the main ways in which larvæ are frequently found by sprinkling ashes round the sanitary pails underground and at all places where people resort when their bowels are to be moved. Fresh cinders are less hostile to larval life than those which have been kept for some time. Creosote kills larvæ very quickly and this suggests the using of cresoted props in the woodwork of mines where there is no danger of fire and the air is moist. The object aimed at in all these measures of disinfection is the destruction of the ankylostoma ova and of the young before they become encysted. Ordinary garden soil is very liable to be infected, but many of the ova found in them through resembling the dangerous ova are in reality harmless. As the encapsulated ova lives largely on material stored up in their own body they can live for months in water apparently without requiring nourishment from the outside. It is to this long power of sustenance on their own bodies that ankylostoma ova owe their capability of long endurance under conditions trying to most other forms of life.

A Simple and Efficient Operation for Hemorrhoids.—N. Porritt thus describes an operation recently performed by him. The sphincter having been stretched, one of the hemorrhoidal masses was seized with vulsellum forceps, pulled well out of the anus and encircled with a loop of loose purse-string suture of Pagenstecher's thread. Above, the suture entered the healthy mucosa beyond the hemorrhoids; below, it took up that just within the anus while at each side it was inserted far enough apart to allow the blades of the crushing instrument to grasp the base or pedicle of the pile seized. For crushing he used an appendicitis clamp, but a pair of hemostatic forceps with blades long enough to overlap the base of the pile would answer. When the clamp is released a broad band of thin tissue connects the pile with the rectum. This pedicle is now folded on itself by giving a half-turn to the pile, the clamp is reapplied, and the crushing is repeated. When the clamp has been removed something like a pedicle has been made, but another half-turn and another crushing leave only a fine pedicle of crushed tissue. The pile is then clipped away through this pedicle, which is tied with a fine ligature beyond the clamp. The stump of crushed tissue with the ligature upon it is then buried by drawing tight and tying the purse-string suture already inserted. Other portions of the mass were isolated and removed in the same way. The patient did well and got up in two weeks after operation. It is now five months after operation and there has been no after-contraction. In order to insert each separate purse string and get a good grip laterally with it a bridge of tissue must necessarily be left between each group of pile dealt with. The little bridge is a safeguard against destroying too much of the involved structures and while not seriously militating against the efficiency of the operation it certainly makes the occurrence of after-contraction improbable.

The External Examination of the Alimentary Canal.—Under this title, L. MacAuliffe describes the proper method of abdominal examination, treating of inspection, palpation, and percussion, and illustrating some of his views by photographs. Nothing essentially new is advanced. The author pretends to think that a new system of examination has been advanced, but either the French, to which nationality the author belongs, are very much behind the times or else we have failed to understand the article, for it contains nothing that has not been in essential details published in every text book of clinical diagnosis for the last five years. Its thoroughness and completeness call for hearty commendation.

Book Reviews.

Introduction to Practical Chemistry. For Medical, Dental, and General Students. Specially adapted to meet the requirements of the Conjoint Boards' examination of the Royal Colleges of Physicians and Surgeons, but suitable for general use in schools and for private students. By A. M. Kellas, B.Sc. (London), Ph.D. (Heidelberg); Lecturer on Chemistry at Middlesex Hospital Medical School; formerly Examiner in Chemistry to the Conjoint Board of the Royal Colleges of Physicians and Surgeons. London: Henry Frowde and Hodder & Stoughton, 1909.

Laboratory manuals do not as a rule make interesting reading. The present volume gives more complete explanations than are usually supplied in such volumes; otherwise it does not differ materially from other works on the same subject. But the book has an interest in that it shows what is required in chemistry at one of the licensing examinations in England. The author has prepared students for these examinations for seventeen years, and he has also served as examiner, so the book may be taken to indicate the requirements pretty accurately.

Textbook of Hygiene. By George H. Rohé, M.D., and Albert Robin, M.D. Fourth Revised and Enlarged Edition. Philadelphia: F. A. Davis Company, 1908.

This book, of 570 pages, not only contains the work of the authors above named, but also that of certain eminent contributors on subjects which partake of the nature of sanitary specialties, such as military, naval, and personal hygiene, and the management of quarantine. The book is divided into twenty chapters, covering the subject in all its phases. There are fifty illustrations, but these are not particularly well selected, and add little to the value of the book.

The text is relatively well balanced, and the questions which appear at the end of each chapter serve to impress the more important features upon the students for whose use the book is especially intended. It seems curious to find a chapter entitled "The Germ Theory of Disease," since the matter of the pathogenicity of disease germs has long since passed from the domain of speculation to that of fact. There is also an unfortunate tendency to quote too largely from the writers of a generation ago rather than from the more illuminating and scientifically exact work of investigators of the present day. The bacterial purification of sewage does not receive as much consideration as its importance warrants, and might well have been illustrated for the benefit of the student. Modern methods for the purification of water by heat are not fully covered, and it would seem that Pettenkofer's theory as to the relation of ground water to the production of disease is given undue importance. The subject of "The Carriers of Infection" could be much enlarged upon with material advantage; plague is not classed with "Diseases of Animals Communicable to Man"; typhoid fever receives scarcely a page of comment, and no mention is made either of typhoid "carriers" or of antityphoid inoculation as a measure of prevention; we find no mention of diphtheria antitoxin in its use as a prophylactic; nor of the use of prophylactic sera in plague and cholera. Tuberculosis, the chief cause of death, is given entirely inadequate consideration, and no mention is made of the various uses of tuberculin in the establishment of early diagnosis. Various other points might be cited to show that the work has not been brought as fully abreast of current knowledge as the date of its publication would seem to warrant. This is unfortunate, as the book has otherwise much to commend it in its announced function as a textbook for students.

Gynécologie Médicale. Traitement médical des maladies des femmes. Par le Professeur Albert Robin et le Dr. Paul Dalché. Troisième Edition, revue et augmentée. Paris: Vigot Frères, Éditeurs, 1909.

The earlier editions of this book have met with marked success in France because of the eminently practical character of its teachings and the authoritative position of the authors in the subject they have chosen. The present edition follows the plan of the earlier issues. The book is divided into five parts, the first two being devoted to a clinical and therapeutic study of the effects of uterine disease upon other systems or organs of the body. These chapters contain a great deal of material that is otherwise scattered through numerous publications dealing with the subject. The menstrual function and its disorders are considered in the third part of the book. Diseases of the vulva, vagina, uterus, and its appendages form the subject of the next chapter, while the last portion of the book is given up to the description of a hydrotherapeutic system of treatment of diseases of women. The therapeutic recommendations throughout the book are specific in character, numerous procedures being fully described and actual prescriptions being given. Conservative treatment in preference to operative interference is given especial attention. The volume is written in the clear and entertaining style that marks French scientific publications, and should prove of interest to American gynecologists.

Essais de Médecine préventive. Par P. Londe, ancien Interne des Hôpitaux de Paris. Paris: Félix Alcan, Éditeur, 1910.

This small volume is an attempt to prove that the great majority of nonspecific diseases of mankind are caused by disturbances in the functions of the gastrointestinal tract. The latter is looked upon as a "laboratory of poisons," and various means of opposing the dangers lurking in it are discussed, regulation of diet and general hygienic measures being, of course, the most important measures both in the prophylaxis and in the therapy of the diseases discussed. Bouchard's theory of autointoxication thus forms the central idea of the book. The main thesis of the author remains far from being proved by the evidence adduced for its support in this book and elsewhere; his discussion, however, is quite interesting, and numerous points of value can be gleaned by the attentive reader. The fact that the book is written in a style and manner calculated to appeal to the laity as well as to the medical profession hardly speaks in its favor; unproven theories are best presented to the circle that is well acquainted with the subject, for otherwise enthusiastic acceptance or opposition of the tenets presented simply serves to hide the partial truth contained in all such discussions.

The Relation of Medicine to Philosophy. By R. O. Moon, M.A., M.D., Oxon., F.R.C.P.; Physician to the National Hospital for Diseases of the Heart; Assistant Physician to the Royal Waterloo Hospital. New York, Bombay, and Calcutta: Longmans, Green & Company, 1909.

To the thoughtful physician for whom the practice of medicine is an art as well as a science there is great fascination in considering the various stages in the development of its underlying principles as we understand them today. For such a reader a work on the history of medicine is more than a mere series of biographies, or rehearsal of scientific discoveries, and he likes to read between the lines something of the general "Weltanschauung" of each epoch and to trace its bearing on the advance of medical knowledge through the effect of the prevailing habits of thought on those engaged in practice or investigation. The present volume is written from this point of view, and while in a way an epitome of the history of medicine it is so in the broadest and most interesting sense. A selection from the chapter headings will give some idea of the manner in which the author develops the subject: The relation of early Greek philosophy to early Greek medicine; influence of early Christianity on medicine; medicine and the renaissance; Arab medicine and Arab philosophy; the effect of philosophy on medicine in the seventeenth century; influence of contemporary thought on medicine in the second half of the eighteenth century, etc. It is dispiriting, and yet also encouraging, to read of the growth, flourishing, and decay of one system of medicine after the other, for on looking back through the centuries it is evident that each of the older errors led to a subsequent approximation to the truth in one direction or the other, with the constant result of actual progress as measured in terms of amelioration of the human lot. This is the conclusion to which the author comes, and the volume in which he records the milestones along this ascent of our art to its present height is one of the most enjoyable it is possible to suggest for the physician's leisure hour.

A Manual of Otology. By Gorham Bacon, A.M., M.D.; Professor of Otology in the College of Physicians and Surgeons, Columbia University, New York. With an Introductory Chapter by Clarence J. Blake, M.D., Professor of Otology in the Harvard Medical School, Boston. New (Fifth) Edition, thoroughly revised. Philadelphia and New York: Lea & Febiger, 1909.

The publisher's statement that this manual is a model of what such books ought to be is no exaggeration. Five editions tell the story. The present edition discards all that has become obsolete and tells of all the advances of modern otology. Among the additions may be mentioned the advocacy of tonsillectomy rather than tonsillotomy, and a brief though complete description of the operation for submucous resection of the nasal septum. Pyelitis is referred to as a complication of acute otitis media, and new illustrations are inserted of the Schwarze-Stacke operation.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 20, 1910.

The President, Dr. John A. Wyeth, in the Chair.

The meeting was held under the auspices of the Section on Pediatrics.

Experimental Epidemic Poliomyelitis.—Drs. Simon Flexner and Paul A. Lewis presented this paper. They said that poliomyelitis had existed in some parts of the United States in the late summer and autumn months since 1907. The cause of the disease was unknown until very recently, and its mode of dissemination had not yet been discovered. Consequently there existed no intelligent means of prevention, but the knowledge of the nature of the disease had been immeasurably advanced by the opportunity for experimental study opened up by the successful transmission of the disease to lower animals. In May, 1909, Landsteiner and Popper published a report of two successful inoculations of monkeys with the spinal cord obtained from two fatal cases of poliomyelitis. The injections were made into the peritoneal cavity. One monkey became paralyzed in the lower extremities, and died on the sixth day after inoculation; the other was killed on the nineteenth day. In both lesions of the spinal cord, similar to those in man, occurred. The disease could not be transferred to other monkeys. Since September they had secured suitable material from two cases of poliomyelitis in human beings. The patient in one instance died on the sixth day after the appearance of the paralysis which affected the lower extremities; the lumbar cord was obtained in a sterile condition twenty-six hours after death and was inoculated into a monkey twelve hours later. The entire spinal cord was obtained in the second case twelve hours after death; the lesions were diffuse throughout the cord. Paralysis had been very extensive. In order to favor the transmission of the disease to monkeys the brain was chosen as the site of inoculation, which was made under ether anesthesia through a small trephine opening. After the inoculation the animals were lively and normal. The injected material consisted of emulsions in salt solution of the spinal cord from the children, and later of the emulsion of spinal cord from monkeys developing the disease. Up to the present time the two viruses had been carried successfully through eleven series of monkeys, and it was regarded as highly probable that the transmission might be carried on indefinitely. Not only was the spinal cord active, but also the cortex of the brain, and still other organs might harbor the active virus. Not all the monkeys developed the disease, even when the inoculation was made into the brain. A delayed or unsuccessful inoculation with one virus might be converted into a successful infection by reinoculation with another, and apparently more active, virus. It could now be stated definitely that it was not absolutely essential that the virus be introduced into the brain, but that successful transmission was possible by way of the peritoneal cavity, by intravascular injection, by subcutaneous injection, and by intraneural injection. The lesions in the monkey in which the virus was introduced into the sheath of the sciatic nerve developed first in the side inoculated and later extended to the opposite side of the spinal cord. It could not be affirmed that still other avenues did not exist whereby the virus might enter into the central nervous system. Additional observations were required before the statement could be ventured that infection might not occur by way of the skin, the respiratory passages, and the digestive tract. It seemed at the present time, however, that it was more difficult to effect infection through these channels. It was entirely clear, however, that no matter which avenue of infection was traversed the virus became established in the spinal cord and medulla, where it set up characteristic lesions which were followed by equally characteristic effects. Not all monkeys which developed the disease succumbed; a certain number recovered in a large measure from the paralysis. There tended to remain, however, residues of paralysis which resembled the paralytic effects persisting in human subjects of poliomyelitis. In their study of the nature of the virus responsible for producing poliomyelitis they had failed utterly to discover bacteria, either in the film preparations or in the cultures. Since in the long series of propagations of the virus in monkeys not one animal showed in the lesions the cocci described by some investigators and they had failed to find any such bacteria in the human material studied, they thought that they could be excluded from consideration. They had made a most painstaking study, but found neither bacterial nor protozoal parasites that could account for the infection. The readiness with which poliomyelitis could be transmitted to monkeys and the failure to find visible and stainable parasites in the lesions led to another line of investigation. It was known that the viruses of vaccinia and rabies withstood the action of glycerin very well, neither of which had been certainly demonstrated in films or sections, while bacteria withstood it far less well. They, therefore, suspended the comminuted spinal cords of monkeys affected with poliomyelitis in glycerin, and after an interval of several days inoculated the glycerinated virus into normal monkeys. These monkeys developed paralysis and showed the characteristic microscopical lesions of epidemic poliomyelitis in the spinal cord and brain. To determine whether this effect was produced by the living virus or by an adherent toxic body, the cord of a monkey which developed the disease after inoculation with the glycerinated virus was injected into a normal monkey, which developed paralysis eleven days after inoculation. The lesions were characteristic. A series of experiments was then planned to determine the probable size of the organism producing epidemic poliomyelitis. The cord of a monkey which succumbed to the fifth generation of virus K was triturated with sterile quartz sand mixed with salt solution, thoroughly shaken and pressed through a Berkefeld filter. The clear and bacteriologically sterile filtrate was injected intracerebrally into a monkey, which developed paralysis on the seventh day following inoculation. That this effect was due to living organisms, and not to soluble toxic bodies, had been shown by transferring the disease to healthy monkeys by means of the spinal cord obtained from monkeys that succumbed to a filtrate. From these experiments it would seem that the infecting agent of epidemic poliomyelitis belonged to the class of minute and filterable viruses that had not thus far been demonstrated with certainty under the microscope. The virus had been shown to be present in the spinal cord and brain, but it had yet to be determined whether it was present in the blood and other organs. They had produced the disease in a monkey by injecting an emulsion of the regional (axillary and inguinal) lymphatic glands communicating with a nodule set up by a subcutaneous injection of the virus that had induced paralysis. Two other monkeys were inoculated at the same time, one from the spinal cord and the other from the local subcutaneous lesion. Both developed paralysis, but the latter after a longer interval. The blood taken at the height of the disease from an affected monkey, defibrinated, and injected into the circulation of a healthy monkey was capable of producing the disease. It had been determined that the spinal cord from a human case of poliomyelitis retained its virulence apparently unimpaired on being kept constantly frozen at $-2°$ to $-4°$ C. in the Frigo apparatus for a period of at least 40 days and also when kept for at least 50 days at a temperature of about $+4°$ C. This indicated that the reduction in the number of cases occurring with the onset

of cold weather did not depend upon the destruction of the virus, although it might have an effect on its multiplication. The spinal cord of a monkey still transmitted the disease after having been suspended for at least seven days over caustic potash in a dessicator. To determine whether the virus could be cultivated artificially, portions of a bacteria-free filtrate were inoculated into bouillon containing 10 per cent. of rabbit's serum which had been rendered perfectly clear and sterile. One cubic centimeter of a filtrate was mixed with nine cubic centimeters of the serum bouillon and incubated. On the second day the fluid in the upper half of the tube was cloudy; the turbidity increased, and on the fourth day the fluid was used for inoculating a monkey, which developed paralysis on the thirteenth day. A single loop of this turbid fluid did not set up turbidity in other tubes of the same medium. A second series of cultivation tests had been made with human ascitic fluid bouillon to which clear filtrates prepared from the spinal cord of affected monkeys were added. In these turbidity developed in twenty-four hours or less, and the turbid fluid inoculated into fresh clear tubes of the same medium caused them to become turbid. None of the turbid fluid contained bacteria that could be seen under the microscope or cultivated in nutrient agar, and the dark field microscope showed no definite bodies. Experiments as to whether an attack of poliomyelitis recovered from afforded immunity to reinfection showed failure of the virus to act, while it produced paralysis in the control monkeys. In seeking for facts relating to artificial protection from or resistance to infection, a considerable quantity of an emulsion of active spinal cord, which had been warmed to 55° or 57° C. for one hour, or 60° C. for one hour, was injected beneath the skin at the same time that the usual intracerebral injection of virus was given. The two monkeys employed in the experiment developed paralysis in the usual manner. Many guinea-pigs and rabbits, one horse, two calves, three goats, three pigs, three sheep, six rats, six mice, six dogs, and four cats had had active virus introduced in the brain without causing any appreciable effect whatever. These animals had been under observation for many weeks. It was to be hoped that the experimental method would solve the question as to the mode of entrance and exit of the virus. In the beginning of the acute stage of the disease in monkeys the cerebrospinal fluid was much altered; it contained an excess of protein, might coagulate spontaneously, and showed under the microscope many lymphocytes. The changes in the fluid depended upon the cellular changes in the membrane. Should it be shown that the cerebrospinal fluid contained the infectious agent of epidemic poliomyelitis, it might be considered probable that the virus passed from the cavity of the skull by way of the lymphatics to the nasopharynx, and that the buccal and nasal cavities were the sources from which the virus was distributed and into which it was received. In other words, that the nasopharynx bore the same relation to the spread of epidemic poliomyelitis as it did to epidemic cerebrospinal meningitis.

Dr. L. Emmett Holt, referring to the clinical features of the disease as it appeared in the epidemic of 1907, stated that they were absolutely identical in symptomatology with those described by Dr. Lewis as occurring in monkeys. The etiology of poliomyelitis was a great puzzle. Small epidemics appeared in widely scattered areas, appearing quickly and disappearing as abruptly as they came. Two years ago, in an attempt to collect data of the various epidemics that had appeared previous to the one of 1907, he was able to learn of but thirty-five, and most of these were small epidemics, and of many the records were poor. Since that year more epidemics had been observed than in all previous time. An interesting question in regard to this new aspect of the disease was that of its frequency: was it more frequent now than formerly, or was it only more generally recognized? Again, was epidemic poliomyelitis as it appeared to-day different from the sporadic form from a study of which our previous knowledge was obtained? Dr. Holt was not certain that the differentiation was at all sharp between the sporadic and epidemic forms of the disease. He thought, however, there had been much confusion in the diagnoses made; also that there had been a great and alarming increase in frequency; but he was not certain that the disease had changed its character. Was Landry's paralysis only a more serious form of the disease, but hitherto not identified as such? So, at least, it now appeared to be. Dr. Holt wished to point out the necessity for more clinical research in poliomyelitis; much work should be done by those who saw the cases, especially in country epidemics, where the association of cases could be determined with some degree of certainty. He called attention to the work the Massachusetts Health Department was doing; every case of poliomyelitis reported to it was investigated. To his own knowledge several epidemics of this disease had occurred in New York State during the past year. The State Board of Health in New York should recognize poliomyelitis as one of the epidemic diseases, and investigate its occurrence wherever it prevailed. The infectious nature of poliomyelitis had been believed for five or six years. Dr. Flexner's researches had now demonstrated it. Was it also contagious? This was a matter about which we could not be certain, but the results of experiments, as well as clinical observations, pointed strongly in that direction. Dr. Holt referred to one instance in the literature in which seven cases of the disease occurred in one family; to three instances in which four cases had occurred in a family; five instances in which three were affected; forty in which two were attacked. In thirty-seven of the cases mentioned the interval between the first and second case was ten days or less. They might then infer that the period of incubation was the same as had been found experimentally in monkeys. Further study of poliomyelitis, both clinical and experimental, could now be based upon definite established scientific facts, and it was to be hoped that future investigation of the disease would bring some tangible practical results.

The Conditions Pertaining to the Safeguarding of Early Life from a Pediatric Point of View.—Dr. Thomas Morgan Rotch of Boston read this paper, which he illustrated by lantern slides. He first reviewed the work which he had already done on the establishment of an anatomical index representing the development of children in the first thirteen years of life, and he showed Roentgen pictures of their wrists. He then showed pictures of children taken from the elementary schools, and gave their heights, weights, school grade, age, and anatomical index. An analysis of these data showed how with a high or low anatomical index, as compared with their age, the children could be graded so as to determine whether they were being forced beyond their resisting powers or, on the other hand, if they could, if necessary, be pushed into a higher grade. Dr. Rotch also explained how important it was to determine the time when children should work in the mills not by age alone, but by a combination of educational standards and age regulated by reference to the anatomical index as obtained by the Roentgen ray. Illustrations were shown of some of the Southern children who were infected with the hookworm, looking as though they were years younger than they really were and yet who, by means of their index, could, if proper laws of development were made, be prevented from working in the mills, even though their age was far above that presented by the laws. Dr. Rotch then spoke of the Roentgen work which, at the request of

the United States Government, he was having carried out at the United States Naval Academy for the purpose of aiding in the proper grading of the cadets. He showed how, with this object in view, he was using the Roentgen ray to determine an anatomical index for older individuals at an age when they were in the Naval Academy, college, technical, and high schools. He stated that, while his Roentgen index had been determined for individuals from one to thirteen years by the order of appearance of the carpal bones and the epiphyses of the radius and ulna, from A to M, he was now presenting merely the lines on which he was evolving the later age anatomical developmental indices. He wished it to be understood that this later index was still merely empirical and not yet worked out as fully as the earlier index, but that there was no doubt but that this later index from N to Z could be evolved just as rationally as the earlier one from A to M. The method of establishing the later index was to determine the time, and thus classify the individual by tabulating in each individual the appearance of the ossification or later union of the epiphyses of the metacarpal bones, the epiphyses of the phalanges, and those of the radius and ulna. He explained that this was not difficult from the age of fourteen up to eighteen or nineteen years, but that after that period much finer Roentgen work would be needed to determine the completion of development by the arrangement of the striæ in the bones at their epiphyseal junctions. Dr. Rotch then showed illustrations of how the Roentgen picture would aid in deciding whether girls at the period of maturity should have their mental and physical work increased or decreased according as their anatomical index showed an advanced vigorous stage of development or an undeveloped condition, irrespective of whether they looked well and were of the average height and weight. He next showed the Roentgen pictures of a set of boys who had entered college at eleven or twelve years of age and were doing the same mental work as boys four or five years older. He explained how their anatomical index indicated whether they were safely undertaking this work beyond their years or not. In some cases the index showed that the individual was absolutely safe in doing such work. One of these cases was a boy of fifteen who had been through Harvard and had taken a *cum laude* and was in one of the post-graduate courses with young men of twenty-two. Although seven years younger than his classmates, his anatomical index showed a development so nearly that of the older individuals that there was evidently no question of his being harmed mentally. Other cases showed the reverse of these conditions. Dr. Rotch also presented the beginnings of some work that he had undertaken on feeble-minded children. Here he had found that such individuals might be of the same height and weight as others of their years and yet their anatomical index corresponded more nearly to their low grade of mental capacity than to their general physical development. He also gave instances of how, from time to time, by taking the Roentgen anatomical index it was possible to determine whether the mental capacity was improving or standing still; this in private practice was often an exceedingly difficult question to answer unless some such aid as the Roentgen ray was invoked. Finally, he showed the Roentgenographs of some twins in which two girl twins showed exactly the same development. Two boy twins also showed the same development, but a twin boy and girl showed that the development of the girl was decidedly in advance of that of the boy. Dr. Rotch stated that these cases supported his view that from birth the development of the epiphyses of the girls was decidedly in advance of the boys, and that this continued so throughout the whole of the child's life, the final union taking place earlier in girls than in boys.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, Held January 7, 1910.

Dr. John W. Brannan, President, in the Chair.

Three Cases of Scleroderma with Resulting Deformities.—Dr. V. P. Gibney presented three patients illustrating scleroderma with deformity of the face and feet, all unilateral and all in girls.

Case I. This patient, aged 5 years, had developed the skin lesion when a year old. The parents observed at this time a peculiar hardening of the skin around the left ankle. As she grew older this hardening had extended up the calf along the outer side, involving the parts supplied by the anterior tibial nerve. The process had gradually extended deeper than the skin, and tendons and fascia were now implicated to the extent of including a talipes valgus. The patient presented a peculiar mottling, hardening, and thinning of the skin covering the dorsum of the foot and the inner side of the leg to the upper third. A patch was found on the inner and posterior aspect of the thigh, but here the skin was alone involved, while on the foot the tendons and fascia were participants, and the peroneals, as well as the common extensors, stood out in bold relief. A peculiar "withering" of the second toe and the fascia on the dorsal aspect, as well as on the plantar aspect of the foot running from the base of this toe, extended string-like in a kind of sulcus to the midtarsal region, narrowing the foot noticeably. The thigh was a little smaller, the knee, calf, and foot markedly so, and measurements showed a decided atrophy. This patient came under observation in September, 1909, and the treatment had been massage and an apparatus to correct the valgus, as yet very inefficient. Dr. George T. Eliot saw her in September and recommended thyroid and hot packs, following massage. Dr. L. Duncan Bulkley also saw her in the hospital and advised the use of nitroglycerin for the benefit of the circulation.

Case II. In the second child, aged 5 years, the first signs were noted about a year ago, no cause being assigned or found. There was a patch over the right shoulder about the size of a quarter of a dollar, another covering two-thirds of the right scapula through the axilla, but movements were free here. There was a patch over the right thorax two inches long and three-quarters inch wide below the clavicle, one the size of a quarter of a dollar to the right of the ziphoid cartilage, an inch from the nipple. The skin was glossy. The whole of the right groin, front of thigh, knee, inner side of leg and foot, completely encircling the ankle, were involved. The skin was mottled. The internal ham strings and adductors of the thigh were involved. There was moderate bow-leg, the knee was not completely extensible, and the foot rested in moderate calcaneus. This case differed in degree only from the first one and might show quite as much involvement of the subcutaneous structures later. The child would be admitted to the hospital, where the treatment could be the better carried out, and where the bow-leg deformity could be corrected.

Case III. A woman, now aged 36 years, came under Dr. Gibney's care about twenty-six years ago, and presented signs very much like those in Case I., except that the left foot, leg, and thigh were involved. The skin was not so seriously damaged as the muscles, tendons, and bones even, for the left lower maxilla was smaller than the right. This case was presented now to this society, about twenty-five years after Dr. Gibney presented it to the Neurological Society, and an oppor-

tunity was afforded for noting an end result. The changes which were now so pronounced, viz., extreme atrophy of the left face, with skin laterally hugging the bony processes, atrophy and hardening of the cervical skin and tendons of the left side, bands of hardened skin at the lower third of the left thigh, outer side, adhering closely to the external hamstring, which stood out in bold relief, and involvement of the left leg, ankle, and foot, an extreme valgus resulting. All of these changes took place during the first five or six years, and since that time all the signs had remained unchanged. So that it could be seen that for the last twenty years the lesion had not made any progress.

End-to-End Intestinal Reunion by the Invagination Method.—Dr. C. L. Gibson showed two specimens of experimental resections on dogs. The method was very simple and dated back to Ramdohs in the eighteenth century, and had been resuscitated from time to time, but had never become a recognized method. The speaker found it an extremely simple and easy method and free from some of the disadvantages of prevailing modes of operation. It was particularly adapted for resections of the sigmoid and upper colon, where Dr. Gibson had employed it successfully in four patients, the first in 1905. The upper segment was telescoped into the lower for a distance of two to six inches. At their point of junction or "neck" the two segments were joined by a series of sutures involving the seromuscular layer only and applied on the Lembert principle, so that the free cut end of the lower end was turned in on itself, giving a broad peritoneal approximation. The experimental work and clinical experience showed a total absence of narrowing of the lumen of the intestine by this procedure.

Demonstration of Various Instruments.—Dr. Gibson demonstrated several new surgical instruments which had recently come into popular use. The first was a new French catheter, which could be boiled indefinitely without any apparent damage to the catheter. He showed one that had been boiled one hundred and twenty times, but on comparison with one that had never been used the old one seemed quite as perfect as the new. They were manufactured from some special preparation of rubber which was said to be practically indestructible. The next instrument was a late improvement on the trephine, which, after grinding the bone and penetrating the inner table of the skull, joined automatically. It was a great improvement over the older trephines, as it did away with the danger of injuring the dura or brain and could be used with greater rapidity in brain operations. Some Gosset self-retaining retractors were also shown and the speaker thought they might become popular, as they were a great improvement over any instrument devised formerly. He also showed a new urethral catheter director, used in external urethrotomy, and a new filiform carrier for passing a filiform from a point below the stricture after Cock's perineal section had been performed.

Heredity.—Dr. Charles L. Dana read this paper. (See page 345.)

Dr. R. Abbe spoke of the surgical aspects of the subject, especially as regards the criminal insane. He mentioned the fact that several States are trying the experiment of castrating both sexes, to diminish their increase by propagation, with very satisfactory results. He cited the case of a negro that he had seen in Richmond, who, before castration, had killed two men and was most refractory and unmanageable, being kept with ball and chain. After the operation he became quiet and tractable and was made a helper in the hospital. More extensive recourse to this procedure among the insane would probably improve the condition of the human stock. Unfortunately such a course has been received very lukewarmly by society and it seems difficult for a legally constituted mind to deprive a man of his important procreative faculties. Possibly unanimity of opinion in the medical profession would bring about a more general acceptance of such a course.

Dr. W. Gilman Thompson asked Dr. Dana about the advisability of the marriage of cousins.

Dr. Dana replied that if the family stock was good and the family history clean as regards disease—especially mental abnormalities—he could see no reason why cousins should not marry. Theoretically it would be safe sometimes even for brothers and sisters to marry. He cited the Egyptian dynasty of the Ptolemies as an example bearing out this latter statement. The danger of close intermarriage lies in the fact that the evil traits in the family stock are likely to become intensified in the offspring. Physicians, before giving advice in such matters, should inquire very carefully into the family history of the individual.

Dr. Janeway said that the transmission of Huntington's chorea, especially in women, was particularly striking and he pointed out the probable influence of heredity in that disease.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Omaha, Neb., December 20 and 21, 1909.

The President, Dr. Arthur L. Wright of Carroll, Iowa, in the Chair.

(*Concluded from page 294.*)

A Scientific Inquiry into the Present Treatment of Peritonitis.—Dr. Arthur E. Hertzler of Kansas City, Mo., reviewed the present treatment of diffuse peritonitis, taking up the various factors which went to make up this treatment and examined them in the light of established facts in abdominal physiology and pathology. He concluded that the explanation of their mode of action had but limited scientific basis. Most of the papers lauding the effectiveness of the modern treatment were unaccompanied by case reports, but those which were so elucidated showed that the favorable prognosis was dependent largely on the fact that cases were included in the statistics which were in no sense diffuse. The present improved prognosis was dependent on earlier diagnosis of the disease, and a more accurate determination of the exact anatomical relation of the disease, making it possible to accomplish the necessary operative work with the least possible traumatism and loss of time. The Fowler position and the introduction of fluids into the body either by vein or rectum, had but a minor influence in the determination of a favorable outcome. In order to facilitate the grouping of cases of peritonitis, he proposed the following classification: 1. The perforative. This group included those cases in which there was expelled into the peritoneal cavity some of the contents of the hollow viscera without there having been any previous protective reaction on the part of the peritoneum. 2. The progressive, in which there was escape of visceral contents into the peritoneal cavity unprotected by adhesions, but in which the peritoneum had undergone a protective reaction. 3. Imperfectly encapsulated. This type joined in the preceding without a sharp line. There were adhesions present in some areas, but there was extension in some directions, *e.g.* along the cecum or into the pelvis in appendicitis. 4. The peritoneal abscess, in which there was perfect encapsulation of the infected area.

Dr. R. C. Coffey of Portland, Ore., said that in acute perforative conditions the point of drainage would depend

largely upon where the perforation had taken place. Another important feature to which he wished to call attention was drainage at the point of suture of the opening. If one sutured a perforated intestine and that intestine was allowed to come in contact with drainage, a fecal fistula would likely result; therefore, it was important to make drainage remote from the point of suture. It was also important that the intestines be lifted away from the drain and the drain not inserted, irrespective of its relation to the intestines.

Dr. Van Buren Knott of Sioux City, Iowa, agreed with Dr. Coffey that the Fowler position had had more to do with recent success in the treatment of diffuse septic peritonitis than any other method.

Dr. Daniel N. Eisendrath of Chicago stated that there were points in the pathology and etiology of peritonitis to which neither Dr. Davis nor Dr. Hertzler had referred, and as a few of these cases had come under his observation during the past three or four years, he thought it might be well to speak of them here. These were the cases in which he had a genuine peritonitis, so far as the pathology was concerned, without visible perforation of the appendix or any other viscus. They were not the cases in which a perforation of the duodenum or stomach had been overlooked, but cases in which streptococci migrated along the lymph channels through the appendix wall and got into the general peritoneal cavity in that way. These cases had occurred not only in his own practice, but in that of others. In looking up a series of cases which they had had at the Michael Reese Hospital in the past ten years, he found there were two of his own, and five others in the practice of Drs. McArthur, Andrews, and Greensfelder. In addition to these, there had been quite a number of cases reported in the literature. They overlooked in little girls a general peritonitis from infective salpingitis. Reidel had recently called attention to this, and had held autopsies on nine little girls who had died of general peritonitis in spite of operation. He found no perforation of the appendix, but simply a very marked and intense salpingitis.

Dr. Chas. H. Wallace of St. Joseph, Mo., said that there was a class of cases that became so septic that one got no drainage, it mattered not what was done. The wound looked like a wound in a cadaver; there was no exudation of serum.

Further Observations on Enterostomy and Its Technique.—Dr. John Prentiss Lord of Omaha, Neb., reported four fatal cases in addition to the four successive successful cases mentioned last year. In one the enterostomy was done for typhoid perforation peritonitis, death being due to the extension of the peritonitis. Numbers two and three were operated on for appendicitis and peritonitis, death resulting from ileus due to peritonitis. Number four was due to septic ileus. The drainage was practically nil, and the condition persisted. Enterostomy was recommended above the line of suture as a vent in resections of the distal half of the large bowel in order to prevent distention from gas which was responsible for the greater number of failures in the suture of this portion of the large intestine. The simple technique by three purse-string sutures about a large catheter was an easy, quick, and ready means of draining the bowel of gas and feces. It was life-saving, and might save some otherwise hopeless cases of obstruction due to peritonitis. The fatal cases reported were extreme ones, and the operation was done as the only remaining recourse.

Some Observations Concerning Intestinal Suture.—Dr. Arthur E. Benjamin of Minneapolis, Minn., in a paper on this subject, drew the following conclusions: "1. Instruments or buttons for making an intestinal anastomosis have practically all been discarded for the suture, as there was less loss of tissue thereby. 2. The purpose of these instruments in the past was to facilitate making an anastomosis and to render the operation more safe. 3. The sutures were to prevent hemorrhage and to approximate like structures until a firm union had taken place, after which they should be absorbed or passed off into the intestines. 4. The side anastomosis was chosen because of the positive blood supply, its safety and ease of performance. 5. The preparation of the patient by carefully selecting the diet, proper attention to waste product elimination, stomach washing, etc., went a long way toward bringing success in these operations. 6. Pagenstecher's thread was largely used for the outside sutures in bowel work. As it was a foreign substance, it might provoke unnecessary adhesions and call for further operative procedures. 7. The linen thread could be used with safety for the inner line of suture, and, when properly placed, prevented hemorrhage of leakage and was soon eliminated. 8. This inner suture should be so placed as to prevent pursing and narrowing of the anastomotic opening. The through-and-through back lock stitch was very suitable for this purpose. 9. The chromic catgut makes an admirable suture for the outer layer and when used as a continuous Lembert, outside of the Pagenstecher lock stitch, a safe and satisfactory union occurs. 10. Care should be observed in performing operations to avoid contamination. 11. The after treatment of the case was very important. Food should not be given too early so as to avoid undue tension upon the suture line."

The Past, Present, and Future of the Western Surgical and Gynecological Association.—Dr. Wright, in his presidential address, referred feelingly to the death of a former president and colaborer, Dr. H. D. Niles of Salt Lake City, and expressed the hope that suitable action would be taken by the members in regard to the loss the association had sustained. The conception of surgeons in the West uniting and forming an association for the sole purpose of discussing questions of interest to them only, originated with Dr. Milo B. Ward of Topeka. The object of the association was primarily the betterment of the members surgically and demanding from the public the respect and confidence their skill merited. This confidence in the ability of each other had done much to make it possible for the surgeon in the small town to relieve serious emergencies with minimum suffering and loss of life. He could not refrain from mentioning the depredating influence of the young specializing in surgery before their mental faculties had fully expanded. This injured the mind and warped the intellect of the student by depriving him of adequate medical and literary training, so essential to the thoroughly equipped surgeon.

Recent Progress in Surgery of Renal Calculi.—Dr. Daniel N. Eisendrath of Chicago stated that much of the progress in recent years in surgery of the kidney was due to the improvement in operative technique, as well as to the ability to secure better skiagraphs of the kidney and ureter. In addition to these two factors the more general employment of ureteral catheterization had added to their knowledge of surgical lesions of the kidney through its ability to enable them to differentiate the various surgical lesions of that organ. In a previous paper he had discussed the pathology and symptoms of renal calculi, so far as the diagnosis could be made from the clinical symptoms. In the present paper he included (*a*) the progress in *x*-ray diagnosis; (*b*) the frequency of bilateral calculi, and their relation to calculous anuria; (*c*) some of the newer points in surgical anatomy of the kidney, and (*d*) the choice of operation for the removal of calculi in the kidney. In regard to the *x*-ray diagnosis Kummell's dictum, "no shadow, no stone," as there were no pathognomonic signs of renal calculi except a positive *x*-ray, did not seem to him too dogmatic, if one included urie-acid calculi, which gave very faint shadows. He called attention to the fact that a long twelfth rib might hide a calculus lying behind it, hence the

necessity of having the radiographs in a diagnostic box. A good radiograph of the kidney would enable one to tell the position, number, and the outline of the shadow. Calculi lying at the pelvic orifice of the ureter had a peculiar nipple-like downward and inward projection, which was very characteristic, and if this shadow was the only one present the operator was usually able to remove the calculus through an incision into the posterior aspect of the pelvis (pyelotomy). Such shadows were placed at a level of the transverse process of the first or second lumbar vertebra, unless the kidney was in its normal position. The second portion of the paper was devoted to the subject of bilateral calculi. He quoted Kummell, who found 16 per cent. of bilateral stones in 101 cases of renal calculi. From a large number of cases of his own and others he found that bilateral calculi occurred in 30 per cent. of the cases. He showed calculi from a bilateral case which was operated upon in two sittings. It was very necessary to recognize the presence of bilateral calculi, not only on account of the anuria, but on account of the reproach incident to the discovery of calculi opposite to the side operated upon. Anuria was a very frequent complication of bilateral calculi. The third portion of the paper was devoted to some recent investigations of his own in regard to the presence of accessory renal arteries. Such a multiplicity of renal arteries, each arising separately from the aorta, occurred in about 30 per cent. of cadavers. There were either two or three separate arteries on each side. This was demonstrated in a number of specimens. The most frequent types were those of separate renal arteries which passed from the aorta to the hilum or where the main renal artery entered the hilum and the second artery entered over the upper or lower pole of the kidney. The arteries of the lower pole might arise from one of the iliac arteries. The condition of multiple arteries occurred more frequently on the right than on the left side. It was very necessary to know the presence of such multiple arteries in connection with all operations on the kidney, especially nephrotomy and nephrectomy, since severe and perhaps fatal postoperative hemorrhage might occur through such an oversight. The last portion of the paper dealt with the question of the best method of removal of calculi from the kidney. If the radiograph showed a single stone at the outlet of the pelvis, and we were certain that this was the only calculus present, the best method of removal was through an incision into the posterior surface of the pelvis, where there were very few vessels, and the extraction of the calculus under those circumstances could be quite readily done. If, however, there were a number of shadows scattered over the kidney area or one large calculus, it was best to remove it through a nephrotomy incision.

Dr. M. L. Harris of Chicago said the need of knowing the condition of both kidneys was very important. The frequency of bilateral kidney stones was a fact which was little recognized by most physicians and by only very few surgeons unfortunately, for the frequency with which some accident happened to the patient after the removal of the first kidney was very great.

Dr. Leonard Freeman of Denver, Colo., said he would like to speak on one embarrassing complication in operating on kidneys for stone, and that was secondary hemorrhage. It was an extremely unfortunate thing to have operated upon a kidney and removed successfully a stone and have the patient go on in the best of condition for a week or ten days and then begin to have a little blood in the urine, a little more the next day, and still more the next. Such hemorrhages were not infrequently fatal. The only thing they could do under these circumstances was to remove the kidney, and the sooner that was done in the presence of secondary hemorrhages the better it was for the patient.

Dr. Arthur C. Stokes of Omaha, Neb., said he had a specimen he should like to show of a stone in the kidney in which case the symptoms were almost none. Preceding the operation for removal of the kidney the patient was operated on, a diagnosis having been made of floating kidney. An incision was made going straight through the muscles of the back, and in the attempt to tie the kidney up to the back a lot of pus was found. The surgeon was not prepared to remove the kidney. The patient subsequently came under his care and the kidney was removed. This patient had practically no symptoms, yet the kidney was almost entirely destroyed.

Movable Liver and Constriction-Lobe of the Liver.—Dr. M. L. Harris of Chicago said that movable liver was found in two classes of patients, namely, those in whom the movable liver was the chief or only abnormal condition present, and those in whom it was but a part of a general visceral ptosis. In the former class the condition was probably due to congenital defects of the attachments of the liver, while in the latter class the loss of the support affected by a firm abdominal wall, together with a gradual yielding and elongation of the attachments of practically all the abdominal organs, played an important part in the condition. Constriction-lobe was a very common condition, being found according to Leue, in 19 per cent. of the male, and 25.3 per cent. of the female subjects over sixteen years of age, autopsied by him, 3,484 in number. Both movable liver and constriction-lobe might give rise to symptoms which were quite distinct and often very distressing, relieved only by properly suturing the liver in place, or by suturing the floating lobe to prevent its abnormal mobility.

Two Cases of Operative Removal of Cervical Ribs.—Dr. S. C. Plummer of Chicago said the first patient was a woman, twenty-four years old. Symptoms began eight years previously and consisted, at first, of pain extending from the axilla to the middle of the ulnar side of the forearm. Four years ago weakness of the hand and later some muscular atrophy appeared. Pain was aggravated by slight exertion. There was no anesthesia. The second patient was a woman, thirty years old, whose symptoms began twenty years ago. Pain in this case was confined to the ulnar side of the forearm. As in the first case, it was aggravated by exertion, but was also brought on by exposure to cold. She also suffered from coldness of the extremity. There was atrophy of the thenar and interossei muscles. There was no anesthesia. Both of these cases had bilateral cervical ribs, as shown by the skiagrams, but in both the symptoms were confined to the right upper extremity. In each case an incision extending obliquely upward and backward for about three inches from just above the right clavicle at the outer border of the sternocleidomastoid muscle, was employed. The first patient now had very little pain, but the strength of her hand had not improved. The second patient was almost entirely free from pain one month after the operation, but was still somewhat sensitive to cold.

Dr. James F. Percy of Galesburg, Ill., said that four years ago he saw three cases of cervical rib in one year, one of them in a girl, fourteen years of age. The second was a girl, sixteen years of age, and in this case the cervical rib was also on the left side, as in the first case. It was discovered by the dressmaker, and the patient came to him because of swelling. The third case was in a girl, twenty years of age, who had the condition on both sides. Not one of these patients had been operated on up to date.

Dr. L. L. McArthur of Chicago had seen a case of double cervical rib, which produced atrophy of the muscles of the hand and double drop-wrist, but unattended by pain. Operation was refused.

Dr. A. F. Jonas of Omaha reported a case of cervical rib in a young woman, twenty-one years of age. She had a swelling in the left side of the neck, which was tender

and hard, and had been diagnosed as sarcoma of the cervical vertebra. The rib could be seen pressing underneath the skin. He cut down upon it and found running over it what he thought was the common carotid artery, but it proved to be the subclavian artery. He reported this case to call attention to the anomalous course of the subclavian artery on the left side, in this particular case.

Dr. Harry M. Sherman of San Francisco reported the case of a woman, thirty years of age, who complained of pain in the arm. Cervical rib was suspected on account of the character of the pain. The rib could be felt, and a skiagraph showed its presence. It was removed, and the pain and disability symptoms disappeared. Later, during pregnancy, the pain had recurred. He was anxious to see whether this pain would disappear after confinement.

Hernia: What Constitutes a Predisposition.—Dr. A. F. Jonas of Omaha, Neb., in his paper, drew the following conclusions: 1. All deductions as to predisposition to hernia that were based on the direction and size of the inguinal canal, a large external ring, were untrustworthy. 2. All opinions as to predisposition based on the vague ideas of muscular weakness, reduced abdominal resistance and diminished support of connective tissue structures, were unreliable. 3. Retarded descent or undescended testicle favored a complete or partial non-obliteration of the vaginal process. 4. A partial or a completely non-obliterated vaginal process might be regarded as an anatomical predisposition to oblique inguinal hernia. 5. The non-closure of the vaginal process could not be recognized clinically. 6. It would seem that we were scarcely justified in using the term predisposition to hernia because of the lack of reliable clinical data.

The Frequency of Congenital Sacs in Oblique Inguinal Hernia.—Dr. William Hessert of Chicago drew the following conclusions: "1. Over three-fourths of all oblique inguinal hernias owed their existence to a preformed sac, the result of some form of faulty closure of the vaginal process in the infant. 2. Congenital malformation of the muscles of this region, as seen in the failure of the internal oblique and transversalis to form a conjoined tendon, was a predisposing cause of both oblique and direct hernias. 3. The lesson to be learned practically from this study was that inasmuch as the hernia owed its existence to a preformed sac, the essential and fundamental act in any hernia operation consisted in the complete ablation of the sac. Avoid the leaving of an infundibuliform process, which might be the cause of recurrence, no matter what the type of operation had been.

Some Anomalies of the Sigmoid.—Dr. L. L. McArthur of Chicago presented the histories of two cases illustrating anomalies of the sigmoid. He was in accord with Dr. Clark in not favoring the fixation by suture of such loops to either the anterior or posterior wall, as the potential dangers were almost equally as great as that of recurrence. Were a similar case to be met with, he would make a side-to-side anastomosis, between the proximal and distal end before restoriug it to the abdomen, just as he had corrected a rectal prolapse by anastomosing the drawn-up rectum to the first portion of the sigmoid.

Preparation of Patients for Prostatectomy.—Dr. E. S. Judd of Rochester, Minn., said the general tendency regarding the preparation of patients for surgical interference was to reduce the details to a minimum, although there were some classes of cases that would do better if they were especially prepared. Because of systemic conditions some patients were not good subjects for operation; on the other hand, the poorest subject would sometimes endure a difficult prostatectomy with considerable loss of blood and be in good condition in a few days. As the gland increased in size the amount of residual urine increased until the back pressure, coming gradually, became a constant factor in the function of the kidney. Continued withdrawal of the pressure would throw the kidneys into a condition of acute congestion, and if they were partially disabled the sudden change might prove very serious, resulting in acute nephritis and suppression. To overcome this difficulty he commenced by emptying the bladder with a catheter at stated intervals, gradually shortening the intervals until the bladder was emptied every hour. In his experience it had not been satisfactory to leave the catheter in the bladder. One ounce of castor oil was given 48 hours before operation. Salt solution per rectum soon after operation was an aid in elimination of the kidneys. The arteries of these patients were hard and inelastic and it was difficult to fill up the circulation; the patients were, therefore, encouraged to take great quantities of fluids for several days before operation.

Lymphangioma, with Report of a Case of Macroglossia and a Case of Macrocheilia.—Dr. A. A. Kerr of Salt Lake City, Utah, stated that where practical, the proper treatment of lymphangioma was excision. In macroglossia, if the swelling interfered with mastication, speech, or deglutition, the proper treatment was partial excision. In macrocheilia, partial or complete extirpation was indicated for cosmetic purposes, as well as a prophylactic measure against infection, or malignant degeneration. In the case reported, by means of a wedge-shaped excision parallel with the long axis of the lip, the latter was reduced to normal size.

Further Experimental Data on the Vasomotor Relations of Shock.—Dr. M. G. Seelig of St. Louis, Mo., stated that in a previous paper he had attacked the widespread doctrine that shock was due to exhaustion of the vasomotor centers, and consequent paralysis of the peripheral vascular system. He rested his case on definite experimental data to prove that the peripheral vascular system was not paralyzed. The present paper was a continuation of the work already reported. The results of his experimental work pointed against the correctness of the theory that shock was a symptom-complex due to vasomotor exhaustion.

Osteomyelitis.—Dr. James E. Moore of Minneapolis stated that inflammation of the bone was due to infection just as it was in any other tissue, the added symptoms and dangers being entirely due to the density of the structure. The virulence of bacteria was always enhanced by pressure and the denser the tissue the greater the danger of necrosis, because of the early interference with the circulation from the products of inflammation, and as soon as part of a bone became necrosed the sequestrum acted as a foreign body. That contusion of bone was the most common exciting cause of osteomyelitis was well established, but that underlying causes were back of that was evident, because all contusions of bone were not followed by infection, and many so-called idiopathic cases occurred with no history of contusion whatever. The early treatment of acute osteomyelitis was just as much of a surgical emergency as the treatment of acute appendicitis. The diagnosis should be made early and followed promptly by operation. There was no medical treatment for this disease, and poultices and other local applications only led to waste of valuable time. There was but one form of treatment, and that was a free opening into the medulla. An incision through the periosteum might relieve some of the pain, but it was insufficient because it failed to stop the ravages of the disease. By a prompt opening into the center of the bone drainage was established and the life threatening poison allowed to escape. An efficient opening relieved the pressure, and when made early enough would stop the separation of the periosteum and destruction of the endosteum, thus preventing or limiting necrosis. In a very early operation no pus might be found, but the medulla was greatly congested and protruded into the wound. Under these conditions the trephine opening

need not be enlarged. Chronic osteomyelitis might be the result of an acute attack or might be subacute from the first, when it was very liable to be mistaken for tuberculosis. In those cases following an acute attack an operation should be performed for the removal of the sequestrum as soon as it was separated, which was anywhere from six weeks to four months. The cavity should be thoroughly curetted, washed, and finally disinfected by heat or 95 per cent. carbolic acid, the latter being much more convenient, and in his experience eminently satisfactory. The acid should be left in the cavity for three or five minutes, when it should be wiped out and the cavity thoroughly washed with alcohol, after which it should he dried and filled with Moorhof's bone wax in a liquid state. The wax quickly hardened at the temperature of the body, after which the periosteum and soft parts were closed in layers by means of chromicized catgut. A dry surgical dressing should then be applied, the bandage being quite snug, and finally the tourniquet should be removed. His experience with the bone wax was such that he could conscientiously recommend it, for when he had temporarily failed he was confident that the fault was in his technique and not in the method.

Extrauterine Pregnancy with Twins, Complicated with Ovarian Fibroid on the Opposite Side.—Dr. D. W. Basham of Wichita, Kansas, reviewed the literature of this subject, and reported a case.

A Deceptive Form of Appendicitis in Women.—Dr. H. S. Crossen of St. Louis, Mo., reported two cases, giving the clinical characteristics, the conditions found at operation, the treatment employed, and the final results. The points of special interest were as follows: "(1) The location of the mass in the tuboovarian region instead of in the appendix region. In the first case, palpation about McBurney's point showed no trouble there, and in the second case simply the edge of the mass extended to the appendix region. (2) The scarcity of inflammatory symptoms. Each patient was sick several months and quite a mass had formed before any acute symptoms appeared, and when they did appear they were comparatively mild. So marked was this feature that the mass, in connection with the history, gave the impression of a new growth, and it was with that diagnosis that each patient came under his care. This is accounted for in a measure by the extreme chronicity of the inflammation and also by its inclusion of the cecal wall, as explained in the next paragraph. (3) The apparent intracecal character of the mass. This was a striking feature and was due to the folding of the cecal wall about the chronically inflamed appendix. Because of the special relation of the appendix to the cecum or because of the chronicity of the low grade inflammation, or both, the infiltration and adhesions affected principally the wall of the cecum adjacent to the appendix. The affected appendix was buried in the overlapped cecal wall. This is what gave the feel of a mass within the cecum, affecting its wall, and it was this also which made it so difficult to locate and expose the appendix. This peculiarity is important from the standpoint of treatment, for, unless carefully investigated, such a condition might be treated by extirpation of the cecum under the mistaken supposition that the mass is intracecal and malignant or tuberculous. This peculiarity helps to account, also, for the dislocation of the mass. As the cecum with its mass was fairly movable it naturally dropped downward into the tuboovarian region. Later, adhesions formed, fixing it in the abnormal location. (4) The slow absorption of the infiltration in the cecal wall, after removal of the affected appendix. In the first case, absorption of the infiltration in the wall of the cecum required nearly a year. In the second case in which pus was found, the absorption of the infiltration was more quickly accomplished, requiring only about five months. Fortunately, in both women the abdominal wall was thin and permitted of deep palpation; consequently the diminution of the cecal induration could be accurately followed. The fact that the condition described is likely to lead to mistakes, is illustrated by the following incidents: In an Eastern museum a specimen labeled 'Absence of the Appendix,' showed on dissection the condition mentioned above, *i.e.* an overlapped cecal wall enfolding the inflamed appendix. Again, in a case related to the speaker, a cecum resected for supposed malignant disease, with fatal result, revealed on subsequent examination the condition above described, *i.e.* the supposed tumor consisted simply of the inflamed appendix surrounded and completely hidden by the cecal wall."

The Abuse of Hypodermic Stimulation During and After Surgical Operations.—Dr. Horace G. Wetherill of Denver, Colo., said the best results and the lowest mortality of the busiest surgeons of to-day were attained by the simplest methods. Careful diagnosis and accurate estimates of the ability of the patient to undergo the operation was made. He was prepared with great care; the anesthetic was wisely chosen and skillfully given; he was operated upon without avoidable exposure, delays, or hemorrhage; he was returned to a warm bed, placed in a favorable position, watched by a competent nurse, and let alone. If he was restless and really suffering from shock or severe pain as he emerged from the anesthetic he might be given a moderate dose of morphine or atropine, but, notwithstanding its stimulating and soothing effect, he was ordinarily better off if it could be omitted.

Surgical Treatment of Hyperthyroidism.—Dr. W. D. Haines of Cincinnati, Ohio, after reviewing the literature, embryology, and anatomy of the thyroid gland, presented evidence to show that the syndrome called goiter was due to over-activity of the adrenals induced primarily by an excess of thyroglobulin in the blood. Discrepancies of opinion in the past were due to a lack of definite knowledge of the actual changes which took place in the gland at the time of observation. Laboratory study had shown a local hyperemia with increase in colloid and diminished staining reaction, but no gross changes in the gland in the first stage. This was followed by hyperplasia, or the second stage. Imperfect alveoli lined with giant cells and great loss in colloid characterized the third stage, while fibrosis, cell atrophy, sclerotic arterial walls, hemorrhage, and cyst formation completed the final steps in the destructive process. Basing treatment upon these findings, he advised diminishing the blood supply by ligating two or more of the thyroid arteries in preference to thyroidectomy in the management of cases of hyperthyroidism, with moderately enlarged gland and active symptoms. Ligation was a lighter operation and was not followed by hypothyroidism. In the operation for the removal of adenoma, or partial thyroidectomy, he kept within the thyroid capsule, thus avoiding injury to the parathyroids and recurrent laryngeals.

Intrathoracic Goiter, with Report of Cases.—Dr. C. H. Mayo of Rochester, Minn., said the transposition of the thymus and lower poles of the thyroid when forming possibly acted as one of the causes of intrathoracic substernal goiter. These growths usually consisted of diffuse colloid or encapsulated adenoma, and when they were completely detached from the thyroid they were wandering. Most of the symptoms occurred from pressure upon the circulation, the trachea, the nerves, or the esophagus. These tumors were usually associated with an ordinary goiter, and probably one-half of them were discovered through complications arising during a thyroidectomy. As they were often enucleated with great difficulty, their removal might be followed by severe hemorrhage. Intrathoracic pressure obliterated the space; therefore, drainage should be brief. Twelve cases were reported, six being of the

diffuse adenoma, six of the encapsulated variety, with one death from collapse of the trachea, due to a hypertrophied thymus of fifty-six grams in a patient with severe hyperthyroidism.

Scopolamine and Morphine as a Preliminary to General Anesthesia; a Report Based on an Experience of Eleven Hundred Cases.—Dr. CLIFFORD U. COLLINS of Peoria, Ill., stated that many erroneous statements had been made in the literature concerning the use of this combination as a preliminary to general anesthesia, and he quoted some of them, which his experience seemed to disprove. He used a tablet containing scopolamine 1/100 grain and morphine 1/6 grain. A solution was made and the combination injected hypodermically one and one-half hours before the operation. The preliminary was given to all adult patients and all children above the age of eight years. No contraindications had been found for the combination. Its action was beneficial as a preliminary to nitrous-oxide gas as well as ether and chloroform, and other general anesthetics. Only one patient in the eleven hundred showed dangerous symptoms, and these were soon relieved. His experience seemed to show that the use of scopolamine and morphine as a preliminary to general anesthesia was a rational procedure, adding greatly to the comfort of the patient by relieving him of all nervous apprehension prior to the administration of the general anesthetic, by permitting him to sleep for some hours after the operation, and by greatly decreasing the amount of post-operative vomiting, and mitigating the dangers of the general anesthetic by lessening the amount necessary to produce the desired effect and by checking the secretion of mucus in the throat.

The following papers were also read: "Duodenal Obstruction, with Uncontrollable Vomiting, and Surgical Method of Treating It," by Dr. Arnold Schwyzer of St. Paul, Minn.; "Specimen Showing Pericolonic Membrane" was exhibited by Dr. Howard Hill of Kansas City, Mo., for Dr. Jabez N. Jackson; "Rhinoplasty with the Aid of a Finger and of Skin from the Chest," by Dr. Harry M. Sherman of San Francisco; "Poliomyelitis, Cause and Best Treatment to Prevent Deformity," by Dr. J. W. Cokenower of Des Moines, Ia.; "Report of a Spinal Cord Tumor," by Dr. William Jepson of Sioux City, Ia.; "Our Present Knowledge of the Pathology of Goiter and Some of the Sequelæ of Its Removal," by Dr. Alanson M. Pond of Dubuque, Ia.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. John P. Lord of Omaha, Neb.; *First Vice-President,* Dr. Harry M. Sherman of San Francisco; *Second Vice-President.* Dr. L. L. McArthur of Chicago, Ill.; *Secretary-Treasurer,* Dr. Arthur T. Mann of Minneapolis, Minn.

Chicago, Ill., was selected as the place for holding the next annual meeting.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEBRASKA STATE BOARD OF MEDICAL EXAMINERS.

Lincoln, November 10 and 11, 1909.

ANATOMY.

1. What arteries unite to form the basilar artery?
2. What arteries, muscles, and nerves would be severed in a cross section at the middle of the humerus?
3. Describe the ulnar artery.
4. Where does the abdominal aorta commence and where does it terminate?
5. Describe the trachea.
6. Name the bones that form the ankle joint, and give their relations.
7. Name the abdominal viscera (*a*) wholly covered with peritoneum; (*b*) those partially covered.
8. Name the regions of the abdomen by diagram.
9. Name five muscles of the back of the leg.
10. Give the origin and insertion and blood and nerve supply of the humeral biceps muscle.

PHYSIOLOGY.

1. What is meant by the term blood pressure?
2. What part of digestion takes place in the duodenum?
3. Describe the pneumogastric nerve, and give its functions.
4. Describe the heart cycle.
5. How is the heat of the body maintained?
6. How are nitrogenous foods digested?
7. Give brief description of special nerve of hearing.
8. Name ductless glands, and give functions of each.
9. What is a carbohydrate?
10. What ferments enter into the digestion of carbohydrate?

CHEMISTRY.

1. Give the chemical name for H_3BO_3; $CHCl_3$; C_6H_5OH; $PbC_2H_3O_2$; $KHCO_3$.
2. How is glycerin obtained, and give its chemical formula.
3. What is the chemical basis of the acidity of normal urine?
4. Describe a test for sugar in the urine. Give a test for bile pigment in urine. What is the normal amount of urea excreted by an adult in 24 hours?
5. Describe oxygen; give its symbol, valence, and atomic weight; tell how to make it.
6. Give symptoms and treatment of poisoning by acetanilide.
7. What is a gas? Laughing gas? Marsh gas? Sewer gas?
8. Name six metals and six non-metallic elements, and the symbol for each.
9. Define oxidation and combustion, and give practical examples of each.
10. Why is a salt of mercury incompatible with potassium iodide?
11. From what sources may chronic lead poisoning come? Give treatment.
12. What are ptomains? Give symptoms and treatment of ptomain poisoning.

Only 10 *to be answered.*

MATERIA MEDICA AND THERAPEUTICS.

1. Define analgesic, anesthetic, hypnotic, and give examples.
2. How does atropine affect the function of (*a*) the eye, (*b*) the heart, (*c*) the intestines, (*d*) the skin? Tell manner of action in each case.
3. What are anthelmintics? Name four, with preparation and dose.
4. Name five official bromides and gives their physiological action.
5. What drug would you use as (*a*) a mydriatic, (*b*) expectorant, (*c*) anodyne, (*d*) escharotic, (*e*) styptic?
6. Give the effect of alcohol on (*a*) the brain, (*b*) the heart, (*c*) the kidneys.
7. Name three drugs that lower temperature, and tell how each does it.
8. Give the source and therapeutic uses of ichthyol and adeps lanæ.
9. Explain the action on the bowel of (*a*) opium, (*b*) thymol, (*c*) bismuth subnitrate.
10. How do saline cathartics produce purgation?
11. What is an alkaloid, a tincture, a fluid extract? Give an example of each.
12. For what purpose and in what doses would you administer (*a*) strychnine, (*b*) calomel, (*c*) tincture of aconite, (*d*) hyoscine, (*e*) potassium iodide?

Only 10 *to be answered.*

PATHOLOGY.

1. What causes rise of temperature?
2. Define hypertrophy; atrophy; give varieties and causes.
3. Give differences between degeneration and necrosis.
4. Give pathology of trachoma.
5. Define gangrene; name the types and give conditions determining each.
6. Describe briefly the reparative process of a fracture.
7. Describe the lesions of typhoid fever, and give distribution of the typhoid bacillus.
8. What forms of appendicitis are usually considered, and describe the structural changes which take place.
9. Define cretinism.
10. Give the pathology of inflammation.

PRACTICE OF MEDICINE.

1. Differentiate between cerebrospinal meningitis and anterior poliomyelitis.
2. Give cause of rickets, diagnosis and treatment.
3. Give urinary findings in parenchymatous nephritis and interstitial nephritis.
4. Differentiate between appendicitis and typhoid fever.
5. In what diseases will the microscope aid us most in diagnosis?
6. Describe the normal heart sounds.
7. Give differential diagnosis of acute glaucoma and acute iritis, and give treatment of each.
8. Give comparative table of contents of cow's milk and woman's milk, and how would you modify cow's milk so that it would compare with mother's milk for a baby six weeks old?
9. What are the symptoms and treatment of catarrhal jaundice?
10. Give cause, symptoms, and treatment of stomatitis.

OBSTETRICS.

1. Give signs of pregnancy.
2. Describe the management of labor in breech presentation.
3. When does the foramen ovale close?
4. Name some of the diseases of pregnancy.
5. Name the varieties of ectopic pregnancy.
6. Define prolapsis uteri. Give pathology, etiology, and treatment.
7. Give some causes and treatment of pruritus vulvæ.
8. What is the difference between menorrhagia and metrorrhagia, and give treatment for both.
9. What is the difference between vaginitis and vaginismus? Give treatment for each.
10. Give etiology and treatment of subinvolution of the uterus.

SURGERY.

1. Define septicemia, and give its causes.
2. How can the danger of ankylosis be averted after injury to a joint?
3. How would you arrest epistaxis?
4. Outline the principle of treatment for a compound dislocation.
5. Give the dislocations of the knee-joint and a method of reduction of any one.
6. What are the indications for trephining in fractures of the skull?
7. How are wounds classified?
8. How would you proceed surgically to remove the fluid in a case of ascites?
9. Give the indications for the removal of the mammary gland.
10. What are the chief surgical diseases of the groin?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEBRASKA STATE BOARD OF MEDICAL EXAMINERS.

Lincoln, November 10 *and* 11, 1909.

ANATOMY.

1. The two vertebral arteries.
2. In a cross-section at middle of humerus, will be severed: *Muscles:* biceps, coraco-brachialis, brachialis anticus, triceps; *arteries:* brachial, superior profunda, inferior profunda; *nerves:* median, ulnar, musculo-spiral, internal cutaneous, musculo-cutaneous.
3. See Cunningham's "Anatomy" (1909), page 834; or Gray's "Anatomy" (1908), page 662.
4. The abdominal aorta *commences* at the aortic opening in the diaphragm and *terminates* on the body of the fourth vertebra, where it bifurcates into the two common iliac arteries.
5. See Cunningham's "Anatomy" (1909), page 972; or Gray's "Anatomy" (1908), page 1384.
6. The ankle joint is formed by the lower end of the tibia and its malleolus, and the external malleolus of the fibula, which together form a mortise above to receive the upper convex part of the astragalus and its two lateral facets.
7. (*a*) *Wholly covered with peritoneum:* Stomach, first part of duodenum, jejunum, ileum, cecum, transverse colon, sigmoid flexure, first part of rectum, liver.
(*b*) *Partiolly covered with peritoneum:* Second and third part of duodenum, ascending and descending colon, middle part of rectum, bladder.
8. See Cunningham's "Anatomy" (1909), page 1046; or Gray's "Anatomy" (1908), page 1246.
9. Gastrocnemius, soleus, flexor longus digitorum, tibialis posticus, and flexor longus hallucis.
10. BICEPS. *Origin:* Short head, from coracoid process of scapula; long head, from upper margin of glenoid cavity. *Insertion:* Back part of tuberosity of radius. *Blood supply:* From brachial artery. *Nerve supply:* Musculo-cutaneous.

PHYSIOLOGY.

1. By the term *blood pressure* is meant the pressure on the blood due to (1) the ventricular systole, (2) the elasticity of the walls of the arteries, and (3) the resistance in the capillaries.
2. In the *duonenum,* proteids, fats, and starches are digested.
3. *Functions of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and œsophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) vasomotor influence to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc."—(Kirkes' *Physiology.*)
For *description,* see Cunningham's "Anatomy" (1909), page 690; or Gray's "Anatomy" (1908), page 1068.
4. The *heart cycle* includes all the changes which occur between the commencement of one heart beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously, and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.
5. The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.
6. Nitrogenous foods are digested in the stomach by the pepsin of the gastric juice, and in the small intestine by the trypsin of the pancreatic juice.
7. See Cunningham's "Anatomy" (1909), page 688; or Gray's "Anatomy" (1908), page 1064.
8. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, cocygeal, pituitary, and pineal glands. The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin. The *function of the thymus* is not settled; it is said: (1) To be a blood forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity. The *function of the thyroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion. The *function of the suprarenals* is not definitely settled; they produce an internal section which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body. The *function* of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.
9. *Carbohydrates* were formerly defined as substances of unknown constitution, consisting of carbon, hydrogen, and oxygen; there being in the molecule six (or some multiple of six) atoms of carbon, and the hydrogen and oxygen being in the proportion to form water.
10. Ptyalin and Amylopsin.

CHEMISTRY.

1. H_3BO_3 is boric acid; $CHCl_3$ is trichlormethane (chloroform); C_6H_5OH is phenol; Pb $(C_2H_3O_2)_2$ is lead acetate; $KHCO_3$ is monopotassic carbonate.
2. Glycerin is obtained by decomposing glyceryl stearate by superheated steam. The *formula* is $C_3H_5(OH)_3$.

3. The acidity of the urine is due to acid sodium phosphate, NaH_2PO_4.

4. Test for *sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. Test for *bile pigment:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

The normal amount of urea excreted in 24 hours is about 500 grains.

5. Oxygen is colorless, odorless, tasteless gas; it is sparingly soluble in water; it has a strong tendency to enter into combination with other elements; it is necessary for respiration, and is both combustible and a supporter of combustion. Its *Symbol* is O; *valence,* 2; *atomic weight,* 16; it is made by heating potassium chlorate:

$$2KClO_3 + \text{heat} = 2KCl + 3O_2.$$

6. *Sympptoms of acetanilid poisoning:* Chilliness, cold sweat; nausea; pulse is soft, slow, and feeble; respirations slow and shallow. *Treatment:* Lavage, diffusible stimulants, application of heat, coffee or strychnine, inhalation of oxygen, or saline infusion.

7. A *gas* is that form of matter in which the molecules tend to get away from each other; it has neither definite shape nor volume. *Laughing gas* is nitrogen monoxide, N_2O. *Marsh gas* is methane, CH_4. *Sewer gas* is the air from sewers, of variable composition, containing emanations from sewage.

8. *Metals:* Lead, Pb; gold, Au; silver, Ag; copper, Cu; zinc, Zn; tin, Sn. *Non-metals:* Hydrogen, H; oxygen, O; nitrogen, N; fluorine, F; chlorine, Cl; iodine, I.

9. By *oxidation* we mean the act of union of oxygen with another element or compound. This process it attended by the liberation of heat, and, when it takes place rapidly, of light. The rusting of a given weight of iron is a slow oxidation, while the burning of the same in oxygen is a rapid oxidation. Only the latter produces light, while in both cases the same amount of heat is liberated.

By *combustion,* in a general sense, is meant the rapid union of the oxygen of the air with some other substance, as coal or phosphorus. In a wider sense, however, combustion may be defined as any chemical union of two substances attended by liberation of heat and light.

10. Both mercurous and mercuric salts enter into double decomposition with potassium iodide, and a soluble iodide of mercury is produced.

11. The most *common sources of lead poisoning* are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."—(Witthaus' *Essentials of Chemistry.*) The *treatment* is first to remove the cause; then administer a purge of jalap and calomel combined with opium; iodide of potassium should also be given to help in the elimination of the lead.

12. *Ptomains* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction. They are found in protein foods which have partly undergone decomposition. *Ptomain poisoning. Symptoms:* Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and occasionally cutaneous eruptions. The prognosis is guardedly favorable. *Treatment* consists in the use of emetics and cathartics, of lavage and rectal irrigation. Morphine may be indicated for the relief of pain, and collapse is to be combatted by atropine, strychnine, nitroglycerin, external heat, whiskey, etc. After thorough purging, salol, naphthol, or bismuth may be given.

MATERIA MEDICA AND THERAPEUTICS.

1. *Analgesic* is an agent which relieves pain by blunting sensation; as opium. *Anesthetic* is an agent which destroys sensation for a period of time; as ether. *Hypnotic* is an agent used to induce sleep somewhat resembling natural sleep: as chloral.

2. *Atropine* (*a*) dilates the pupil and causes disordered vision; it stimulates the end organ of the sympathetic, and paralyzes those of the motor oculi nerve. (*b*) It increases the rate (but not the force) of the heart by depressing the vagus. (*c*) Intestinal peristalsis is increased by its action on the splanchnic nerves. (*d*) The skin is flushed and rendered dry by its paralyzing action on the nerve endings in the sweat glands.

3. *Anthelmintics* are agents which kill or expel worms. *Examples:* Oleoresina aspidii, gr. xxx; Pelletièrine tannate, gr. x; santonin, gr. j; pumpkin (pepo) seeds, ʒj.

4. Bromide of potassium, of sodium, of lithium, of ammonium, of calcium. *Physiological action:* Depressants of circulatory and nervous systems; hypnotic, analgesic; muscular depressant; lower arterial tension and body temperature; anaphrodisiac.

5. (*a*) *Mydriatic,* Atropine; (*b*) *Expectorant,* Ipecac; (*c*) *Anodyne,* Opium; (*d*) *Escharotic,* Silver nitrate; (*e*) *Styptic,* Alum.

6. (*a*) On the *brain,* alcohol first acts as a stimulant; the nerve centers, imaginations, feelings, intellect are all exalted; the centers of speech and muscular movements are stimulated; afterwards they may be depressed. (*b*) On the *heart,* alcohol causes increase in the force and frequency, dilatation of the peripheral blood-vessels. (*c*) On the *kidneys,* alcohol acts as a diuretic.

7. (1) *Alcohal* lowers body temperature by diminishing tissue change, and also by dilating the cutaneous vessels, thus increasing heat radiation. (2) *Aconite,* by reducing the circulation. (3) *Acetanilid,* by diminishing tissue change, and also by promoting perspiration.

8. ICHTHYOL. *Source:* A quartz containing the fossilized remains of fish. *Therapeutic uses:* Skin diseases (eczema and psoriasis), to remove inflammatory processes and their products. ADEPS LANÆ. *Source:* Sheep's wool. *Therapeutic uses:* As a basis for ointments, in various skin diseases, chaps, burns, frostbites, and as a vehicle for morphine and other anodynes.

9. (*a*) *Opium* is a sedative to the intestine, secretions are dried, pain is relieved or prevented, peristalsis is slowed or arrested. (*b*) *Thymol* is an intestinal antiseptic, and an anthelminthic in ankylostomiasis. (*c*) *Bismuth subnitrate* is sedative and astringent.

10. Saline purgatives cause a great increase in the amount of fluid secreted by the intestinal glands; they also hinder the reabsorption of this fluid. The result is an accumulation of fluid in the intestine, which, by distention, excites peristalsis.

11. An *alkaloid* is an organic nitrogenized substance, alkaline in reaction, and capable of reacting with an acid in the same way that ammonia does. Example, strychnine. A *tincture* is an alcoholic solution of a non-volatile medicinal substance. Example, tincture of aconite. A *fluidextract* is a solution of vegetable drug of such strength that 1 c.c. of the fluidextract represents one gram of the drug. Example, fluidextract of belladonna.

12. (*a*) *Strychnine,* as stimulant to cardiac, respiratory, nervous, or muscular system. Dose, gr. 1/64. (*b*) *Calomel,* in glandular inflammations of throat and neck, irritable stomach, diarrhea, dysentery, gastric ulcer. Dose, gr. x; but often best given in divided doses. (*c*) *Tincture of aconite,* in coryza, tonsillitis, fevers, pleurisy, meningitis, peritonitis, pneumonia, rheumatism. Dose, ♏v of the tincture; but divided doses are often better. (*d*) *Hyoscine* in mania, insomnia, hallucinations, delirium, whooping cough, irritability of the bladder, as a hydriatic. Dose, hyoscine hydrobromide, gr. 1/150. (*e*) *Potassium iodide* in tertiary syphilis, neuralgia, paralyses, mercurial poisoning, after pneumonia, pleurisy, or pericarditis, aneurysm, hay fever, tonsillitis, asthma. Dose, gr. vijss.

PATHOLOGY.

1. *Rise of temperature* is caused by: Disturbances in the thermogenetic, thermolytic, or thermotactic centers; excessive heat; toxic substances; infectious diseases.

2. *Hypertrophy* is an increase in the size, weight, and functional activity of a part beyond the limit of health, due to an orderly enlargement or multiplication of all its normal constituents. *Varieties:* (1) Simple, when only the size of the element is increased; (2) *Numerical,* when the number also is increased. *Causes:* (1) Excessive vital energy; (2) increased work; (3) increased blood supply; (4) diminished waste; (5) removal of resistance to growth.

Atrophy is decrease in the amount of a tissue, owing to diminution in size (simple atrophy) or number (numerical atrophy) of the histological elements of which it is composed. There is also loss of weight, and impairment of function. *Varieties:* Simple and numerical (see above); also general and local. *Couses:* (1) Deficient supply of nutrition; (2) excessive waste; (3) impaired vital activity;

(4) diminished functional activity; (5) pressure; (6) sometimes excessive functional activity.

3. In *necrosis* the tissue is dead; in *degeneration* its vitality remains, but is lowered, and the function may remain in an impaired state.

4. Trachoma is infectious, but the causal germ is not identified. There are follicles on the conjunctiva, which become granular masses and spread over the surface of the entire lid. Ulceration takes place, and the necrosed membrane is replaced by scar tissue.

5. See Rose and Carless' "Surgery" (1908), pages 98 and 102; or Da Costa's "Surgery" (1908), page 168.

6. See Rose and Carless' "Surgery" (1908), pages 472 and 481; or Da Costa's "Surgery" (1908), page 457.

7. See French's "Practice" (1907), pages 70 and 69; or Osler's "Practice" (1909), pages 65 and 60.

8. See French's "Practice" (1907), page 789; or Osler's "Practice" (1909), page 513.

9. *Cretinism* is a congenital condition, marked by mental hebetude and imbecility, imperfect development, and deformity of the whole body. It is said to be due to congenital absence or functional inactivity of the thyroid gland.

10. See Rose and Carless' "Surgery" (1908), page 30; or Da Costa's "Surgery" (1908), page 73.

PRACTICE OF MEDICINE.

1. See French's "Practice" (1907), pages 146 and 1035; or Osler's "Practice" (1909), pages 163 and 916.

2. See French's "Practice" (1907), page 932; or Osler's "Practice" (1909), page 426.

3.

ACUTE PARENCHYMATOUS NEPHRITIS.	CHRONIC PARENCHYMATOUS NEPHRITIS.	CHRONIC INTERSTITIAL NEPHRITIS.
1. Urine scanty, dark or smoky color, high specific gravity, 1025 or over.	1. Urine normal or increased amount; specific gravity may fall to 1010; urine pale.	1. Urine greatly increased; specific gravity low, 1005; urine pale in color.
2. Large amount of albumin.	2. Late in attack, greatly diminished; occasionally absent.	2. Albumin greatly diminished, often absent.
3. Variety of casts, such as hyaline, blood, epithelial, and waxy casts, also free red blood globules, and epithelial cells.	3. Large and small granular casts; compound granule cells, and fatty epithelium.	3. Hyaline or finely granular casts, occasionally dark in color; infrequently blood casts and oil droplets.
4. Urea diminished.	4. Urea diminished.	4. Urea diminished.

4. Typhoid fever is distinguished from appendicitis by its (typhoid's) more gradual onset, characteristic temperature record, diarrhea, enlargement of the spleen, rose-colored rash, and boidal reaction.

5. Typhoid, malaria, cerebrospinal meningitis, diphtheria, gonorrhea, anemias, leukemias, nephritis, Hodgkin's disease, tuberculosis, empyema, filariasis, anthrax, hydrophobia, syphilis, leprosy.

6. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup*. The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) the vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The *second* sound is caused by the vibration due to the closure of the semilunar valves.

7.

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy and steamy surface.	Cloudy.
Anterior chamber.	Shallow.	Unchanged.
Pupil	Dilated, oval.	Contracted, synechiæ.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.
Treatment	Eserine, pilocarpine, iridectomy.	Atropine.

Treatment of glaucoma: Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

Treatment of iritis: Atropine, dionine, the application of leeches to the temples, hot fomentations, absolute rest in bed, protection from the light, light diet, purgatives, abstinence from alcohol, avoidance of all use of the eyes for near work, constitutional treatment varying according to the etiology, paracentesis, and iridectomy.

8.

	WOMAN'S MILK. *Average Per Cent.*	COW'S MILK. *Average Per Cent.*
Fat	4.00	4.00
Sugar	7.00	4.50
Proteids	1.50	3.50
Salts	0.20	0.75
Water	87.30	87.25
	100.00	100.00

To make cow's milk resemble human milk: The cow's milk must be diluted and sugar of milk must be added. These modifications must be made in such proportions as to bring the percentage composition of the two milks as near alike as possible.

9. See French's "Practice" (1907), page 843; or Osler's "Practice" (1909), page 543.

10. See French's "Practice" (1907), page 707; or Osler's "Practice" (1909), page 434.

OBSTETRICS.

1. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle. *Doubtful signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness. *Subjective signs of pregnancy,* in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements. *Objective signs of pregnancy,* in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

2. See Williams' "Obstetrics" (1909), page 290; or Hirst's "Obstetrics" (1909), page 425.

3. The foramen ovale closes any time between the first week and the sixth month of extrauterine life.

4. See Williams' "Obstetrics" (1909), page 480; or Hirst's "Obstetrics" (1909), page 215.

5. *The varieties of ectopic pregnancy* are: Interstitial, tubal, ovarian, and abdominal.

6. Prolapsis uteri. *Definition:* A condition in which the uterus sinks below its normal level, but does not protrude through the vagina. *Pathology:* "Decrease in the power of uterine support. Distention and eversion of the vagina with decrease in the power of its sphincter and thickening of its epithelium. The uterus is enlarged from impairment of its circulation, its cavity is increased in size, and hyperplasia of its areolar tissue may result. The endometrium becomes thickened, congested, and inflamed. Ectropion may occur. Varicose degeneration of the vessels of the cervix may take place with consequent absorption of its proper tissue; ulceration may also occur. Pelvic congestion from compression of the hypogastric veins. Tension on the broad ligaments may produce obstruction of ureters and hydronephrosis. Occasionally, epithelioma from continued irritation of the cervix. Varicocele of the pampiniform plexus from torsion of the broad ligaments. When cystocele is present, complete evacuation of the bladder cannot be obtained, and the result is dysuria, ardor urinæ, and cystitis or retention of urine."

Etiology: Injury at childbirth, lacerated perineum, re-

laxation and elongation of the ligaments of the uterus, loss of rigidity of the abdominal walls, increase in the weight of the uterus, subinvolution, increased intraabdominal pressure. *Treatment:* "Operative, unless some contraindication to operation exists. In such a case some *mechanic device* should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by Braun's colpeurynter. This is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter well anointed with carbolized vaseline and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations. *Operative treatment* gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the perineum will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina. The best of these is Martin's operation for cystocele. If the cervix is hypertrophied it should be amputated. Three operations—on the perineum, for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hystrorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, hysterectomy may be performed."

7. Pruritus vulvæ may be *caused by:* Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic. *Treatment* consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of bichloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

8. *Menarrhagia* is an excessive loss of blood at the menstrual periods. *Metrarrhagia* is a hemorrhage from the uterus at other than the menstrual periods. It is very often impossible to differentiate the two conditions. *Treatment:* Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium; rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used.

9. *Vaginitis* is a condition of inflammation of the vagina. It is characterized by redness, swelling, pain, heat, irritation, and increased secretion. There may be frequent and painful urination. *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

10. Subinvolution. *Etiology:* Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus. *Treatment:* Rest in bed, hot intrauterine and vaginal douches, correction of constipation, abstention from sexual intercourse, tonics, correction of displacement, curettage. An abdominal binder may be worn.

SURGERY.

1. *Septicemia* is an acute general infection arising from the presence of pyogenic microorganisms in the blood. *Causes: Streptococcus pyogenes* or other pus-producing bacteria which spread from a primary focus through the lymphatics or by an eroded vessel into the blood current.

2. *Ankylosis may be averted* by: Limiting the effusion or inflammatory exudate; by early passive movement to prevent the union of synovial surfaces; by massage; by removal of loose cartilages and hypertrophied synovial fringes.

3. *To arrest epistaxis:* (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

4. Rose and Carless' "Surgery" (1908), page 617.

5. Rose and Carless' "Surgery" (1908), page 634; or Da Costa's "Surgery" (1908), page 604.

6. Rose and Carless' "Surgery" (1908), page 751; or Da Costa's "Surgery" (1908), page 708.

7. *Wounds are classified* as:

I. Contused and open wounds.

II. Open wounds may be: Incised, lacerated, contused, punctured, gunshot, or poisoned; also penetrating and perforating.

III. Aseptic and septic.

8. Rose and Carless' "Surgery" (1908), page 984.

9. *Indications for removal of mammary gland:* Enormous hypertrophy, Paget's disease of the nipple, epithelioma of the nipple, carcinoma, sarcoma, cystic adenoma, diffuse tubercular or septic disease if breast is riddled with sinuses.

10. *Chief surgical diseases of the groin* are: Hernia (inguinal, femoral, or obturator), aneurysms, tumors, cysts, ulcers, sinuses, abscesses, enlarged glands, undescended testicle, prolapsed ovary.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	June —
Arizona*	Ancil Martin, Phoenix	Phoenix	April 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 5
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 8
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	April 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	April 4
Georgia	E. R. Anthony, Griffin	Atlanta	April —
Idaho*	W. F. Howard, Pocatello		April 5
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	July 12
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	F. P. Hatfield, Olathe	Topeka	June 14
Kentucky	J. N. McCormack, Bowling Green	Louisville	July —
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 17
Maine	F. W. Searle, Portland	Portland	Mar. 8
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 7
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Mar. 8
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 14
Minnesota	W. S. Fullerton, St. Paul	St. Paul	May 10
Mississippi	S. H. McLean, Jackson	Jackson	May 10
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	June 13
Montana*	Wm. C. Riddell, Helena	Helena	April 5
Nebraska	C. A. Carr, Lincoln	Lincoln	Aug. 3
Nevada	S. L. Lee, Carson City	Carson City	May 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	July 6
New Jersey	H. G. Norton, Trenton	Trenton	June 21
New Mexico	J. A. Massie, Santa Fe	Santa Fe	April 11
New York	C.F.Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	May 24
N. Carolina	B. K. Hays, Oxford	Wrightsville	June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 4
Ohio	Geo. H. Matson, Columbus	Columbus	June 14
Oklahoma*	F. P. Davis, Enid	Guthrie	April 12
Oregon	B. E. Miller, Portland	Portland	July 5
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	June —
Rhode Island*	G. T Swarts, Providence	Providence	April 7
S. Carolina	H. H. Wyman, Aiken	Columbia	June —
S. Dakota	H. E. McNutt, Aberdeen	Watertown	July 13
Tennessee	C. A. Abernathy, Pulaski	Memphis, Nashville, Knoxville	May —
Texas	M. E. Daniel, Honey Grove	Austin	June 28
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	April 4
Vermont	W. Scott Nay, Underhill	Burlington	July 12
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	T. C. McFadden, Seattle	Spokane	July 5
W. Virginia	H. A. Barbee, Point Pleasant	Wheeling	April 12
Wisconsin	J. M. Beffel, Milwaukee	Madison	July 12
Wyoming	S. B. Miller, Laramie	Cheyenne	

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Pennsylvania.—Of 71 applicants for license to practise medicine in the State of Pennsylvania examined December 28, 65 were successful. The necessary average, beginning with 1910, will be 70 per cent., instead of 60 per cent., as heretofore.

Texas.—Reciprocity with Arkansas has been arranged on the following basis: Arkansas is to accept Texas practitioners licensed by written examination since July 12, 1907; and Texas to accept those from Arkansas licensed in like manner since August 6, 1909.

Vermont.—After January 1, 1911, candidates will not be admitted to examination who have not received, as part of their medical education, instruction in simple refraction.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RÖNTGENATLAS DER LUNGENTUBERKULOSE. Von Dr. OTTO ZIEGLER und Dr. PAUL KRAUSE. 8vo; cloth. Curt Kabitzsch (A. Stuber's Verlag), 1910.

JEJUNAL AND GASTROJEJUNAL ULCER. By HERBERT J. PATERSON, M.A., M.B., B.C. Cantab., F.R.C.S. Eng. 4to; cloth; 72 pages. John Bale, Sons & Danielson, Ltd., London, England.

SPONDYLOTHERAPY. By ALBERT ABRAMS, A.M., M.D. (Univ. of Heidelberg), F.R.M.S. 8vo; cloth; 400 pages; illustrated. The Philopolis Press, San Francisco, Cal.

EXPERIMENTAL PHYSIOLOGY. By ALCOCK and ELLISON. 8vo; cloth; 139 pages; illustrated; $1.50 net. P. Blakiston's Son & Co., Philadelphia, Pa.

MEDICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D., Ph.G. 8vo; cloth; illustrated; 734 pages; $3 net. P. Blakiston's Son & Co., Philadelphia, Pa.

A COMPOUND OF HISTOLOGY. By HENRY ERDMANN RADASCH, M.S., M.D. 12mo; cloth; 350 pages; illustrated; $1 net. P. Blakiston's Son & Co., Philadelphia, Pa.

HEART DISEASE, BLOOD PRESSURE, AND THE NAUHEIM-SCHOTT TREATMENT. By LOUIS FAUGERES BISHOP, A.M., M.D. 8vo; cloth; 284 pages; illustrated; $3; E. B. Treat & Co., New York.

EXAMINATION OF THE URINE. By G. A. DE SANTOS SAXE, M.D. 12mo; cloth; 448 pages; illustrated; $1.75 net. W. B. Saunders Co., Philadelphia, Pa.

The Wassermann Reaction in Different Periods of Syphilis.—P. Minassian and O. Viana, after experiments on the application of the Wassermann reaction in sixty syphilitic patients, find that the reaction is much more often positive after the primary stage, being present in from 83 to 86 per cent. of cases in the secondary and tertiary stages of the disease, while positive in only about 25 per cent. of primary cases. Its presence is a positive evidence in favor of syphilis, while its absence does not demonstrate the absence of this infection. As antiagents the extract of syphilitic liver gives the most constant results. The syphilitic antibodies are found in the milk, amniotic fluid, pemphigus bullæ, and hydrocele of syphilitic patients. Mercurial treatment has little effect on the presence of the reaction. In non-syphilitic individuals the search for antibodies is always negative.—*Folia Ginecologia,* Vol. II., Part I, 1909.

The Artificial Nursling.—V. Wallich describes a new form of breast pump, in which there is a return current of air with each stroke of the aspirating piston, thus simulating the nursing of the infant. It is of use in cases of badly shaped nipples, cracks, lymphangitis, and abscess of the breast, in debility of the new-born, in diseases such as convulsions, and in hare-lip. The author has made practical use of this pump with success. The mother may use it herself by means of a stirrup which holds the pump in place and allows her to pump with one hand and hold the reservoir against the breast with the other. It allows of mixed feeding, mother's milk and cow's milk at the same time. A considerable amount of milk may be obtained in a few minutes without pain to the mother, and may be fed to the infant with a spoon or a bottle.—*Annales de Gynécologie et d'Obstetriques,*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 18, 1910:

SOME PHASES OF THE EVOLUTION OF MODERN PREVENTIVE MEDICINE, AS ILLUSTRATED BY THE PRESENT CAMPAIGN AGAINST TUBERCULOSIS.*

BY GERMAN SIMS WOODHEAD, M.A. (Cantab.), M.D. (Edin.), LL.D., (Toronto).

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF CAMBRIDGE, ENGLAND.

WHAT a change has come over our conception of tuberculosis within quite recent years! During the last few days a keen controversy has been raging over a matter that some years ago appeared to be definitely settled—the amount and importance of the infection of the human subject by the tubercle bacillus of bovine origin. That tuberculosis can be transmitted from the bovine to the human subject had been very generally accepted. Following Koch in his original investigations, Baumgarten, Straus, Watson Cheyne, Klein, Bang, and others, most investigators had accepted the tubercle bacillus, whether met with in man or the lower animals, as the prime causal agent in the production of tuberculosis in these various species. Indeed, the matter appeared to be finally settled when Smith, Dinwiddie, and Frothingham first threw doubts on the unity of the virus. Their attitude in this matter was soon more than confirmed by Koch, who, working with Schutz, came to a conclusion which he announced in the following words: "Considering all these facts, I feel justified in maintaining that human tuberculosis differs from bovine, and cannot be transmitted to cattle. It seems to me very desirable, however, that these experiments should be repated elsewhere, in order that all doubt as to the correctness of my assertion may be removed," and "though the important question whether man is susceptible to bovine tuberculosis at all is not yet absolutely decided, and will not admit of absolute decision to-day or to-morrow, one is nevertheless already at liberty to say that, if such a susceptibility really exists the infection of the human being is but a very rare occurrence. I should estimate the extent of infection by the milk and flesh of tuberculous cattle, and the butter made of their milk, as hardly greater than that of hereditary transmission, and I therefore do not deem it advisable to take any measures against it."

After indicating that if it were possible to find a considerable number of cases of primary tuberculosis of the intestine which might reasonably be ascribed to infection by a bacillus of bovine origin, he gave some figures which, if corroborated by other observers, would lend very great support to his thesis that bovine tuberculosis is practically a negligible quantity as regards the infection of the human subject. He says, "but such cases"—of so-called primary tuberculosis of the intestine—"are extremely rare. Among many cases of tuberculosis examined after death, I myself remember having seen primary tuberculosis of the intestine only twice. Among the great post-mortem material of the Charité Hospital in Berlin ten cases of primary tuberculosis of the intestine occurred in five years. Among 933 cases of tuberculosis in children at the Emperor and Empress Frederick's Hospital for Children, Baginsky never found tuberculosis of the intestine without simultaneous disease of the lungs and the bronchial glands. Among 3,104 post-mortems of tuberculous children Biedert observed only sixteen cases of primary tuberculosis of the intestine."

More than twenty years ago I published the results of a series of examinations of cases of tuberculosis in children. I had the opportunity of making post-mortem examinations of 127 such cases that had died in the wards of the Royal Edinburgh Hospital for Sick Children. Among these I found 43 in which there was tuberculous ulceration of the intestine. Only one had succumbed during the first year after birth; 14 died within two and a half years after birth; 10 between three and five years; 7 between six and seven and a half years; 5 between eight and ten years, and 6 between eleven and fifteen years. Although there was such tuberculous ulceration in 43 cases only, there was distinct tuberculous affection of the mesenteric glands in no fewer than 100, or in nearly 79 per cent. of the whole. It struck me as significant that these tuberculous glands were found in a very large proportion of those who succumbed to disease after the first year of life. During the first year of life there were 4 cases only; from one to two and a half years, 33; from three to five and a half years, 29; from six to seven and a half years, 12; from eight to ten years, 13, and from eleven to fifteen years, 9. In fourteen of these cases the mesenteric glands only were affected, *i.e.* no tubercle was found in any other part of the body. Moreover, more than half of them in which no other tuberculous lesion was found were patients who had succumbed between the ages of two and five and a half years. Since these figures were published Still, Shennan, and the Royal Commissions on Tuberculosis in England and in Germany have given out similar statistics, similar in so far, at any rate, that in the main they agree with those I have given. Bearing on this point Dr. Still found that of the cases of tuberculosis that came to the post-mortem table in the Hospital for Sick Children, Great Ormond street, London, 29.1 per cent. of the cases presented evidence of primary infection having taken place through the intestine. Dr.

*The Wesley M. Carpenter lecture, delivered before The New York Academy of Medicine, October 8, 1908.

Shennan, who continued my own investigation, estimated that 28.1 per cent. of the cases of tuberculosis among children in the Royal Edinburgh Hospital for Children are due to alimentary infection.

I mention my own figures simply because they constitute the factor that influenced my early work and possibly have even biased some of my later conclusions. They afford evidence, however, collected long before (and therefore having no calculated bearing on the point then raised) Dr. Koch gave his London address, that primary tuberculosis mesenteric glands were in the years 1875-1887, in Scotland at any rate, considerably more numerous than apparently they were in Germany at a somewhat later period, when special search was made for them.

Principal McFadyean, following Dr. Koch, commenting on the figures given by Still and Shennan, held that "there does not appear to be any ground for supposing that there is a large marginal error in these statistics, as the number of cases dealt with was considerable, 547 in the two series. In face of these statistics it is not possible to assent to the statement that cases of primary tuberculosis of the alimentary canal are extremely rare. Precisely the contrary conclusion is the one that must in the meanwhile be drawn with regard to the state of affairs in this country, viz., that at least in children primary infection is by way of the alimentary canal."

Lord Lister clinched the matter from the practical point of view when he stated "that which has, perhaps, most riveted the attention of us all has been the startling thesis that bovine tuberculosis is incapable of development in man. This is a matter of the most enormous importance. On the one hand, if this conclusion is correct, our means of prevention of tuberculosis will be greatly simplified. On the other hand, it would be a very serious and very grievous matter if the endeavors that are being made to provide purity of milk supply should be relaxed, and then, after all, it should turn out that the conclusion was not altogether correct."

As bearing on the question of "specificity or modification," Lord Lister quoted the example of the extreme difficulty of inoculating smallpox in the calf. Isolated successes had been recorded, but "the failures so greatly preponderated that pathologists of the highest eminence came to the conclusion that smallpox and cowpox were totally distinct diseases. It has now been shown that this was an entire mistake." Quoting Dr. Monckton Copeman, he pointed out that, although it is impossible to inoculate smallpox from man into a calf, this can infallibly be done from man to the monkey and then from the pustule in the monkey to the calf in which a typical cowpox pustule is then invariably produced; from this a genuine cowpox vaccination for the protection and prevention of smallpox in the human subject may be carried out. A virus which is practically incapable of direct inoculation from man into a certain other species, becomes so altered in its properties by passage through a third species of animal that it will grow readily in that in which it could previously develop only with great difficulty," and when so modified can be transferred back to man with the utmost facility. Therefore this matter is one that requires its own special demonstration. It does not at all follow, because human tuberculosis will not develop in the cow, that therefore bovine tuberculosis may not develop in man."

These observations brought forward, and the discussion that followed, were deemed to be so important that men in all countries took up the matter. You in America were first in the field, but we in England and our friends in Germany pressed hard on your heels and went into the questions raised with both method and enthusiasm. Our Royal Commission was formed and from the moment that the commissioners were called together the work of inquiry has continued without a single intermission.

As you will readily understand, the members of the British Royal Commission have, without exception, always assumed that any work coming from Koch's laboratory deserves and must receive the most careful consideration and that any suggestions he may make, or indication he may throw out, must be most judicially weighed. Moreover, we accept it that as regards actual observations, he is quite as, perhaps even more, likely to be right than any single one of us. Further, we are all agreed that we must have unexceptionable evidence of the accuracy of our observations before we can be thoroughly satisfied as to their correctness should they run counter to what has been published by Koch and his pupils. We are now satisfied that Koch has materially underestimated the danger of bovine sources of tuberculous infection. A number of new problems have, however, been brought up for solution, problems which must have come to the front, even had not the discovery of the tubercle bacillus rendered them imminent.

May I now be allowed to make a very brief statement as to what has been reported by the British Royal Commission on Tuberculosis? First, it has brought out the fact that 50 milligrams of any culture of the *Bacillus tuberculosis* from bovine sources always produces a fatal generalized progressive tuberculosis and almost invariably proves fatal within ninety days (eighteen out of twenty experiments); that a dose of 10 milligrams was also fatal in the case of many of these viruses, but in one case there was merely a minimal infection. It is important to bear this one case in mind. Using an emulsion of tissue containing the type of bacillus coming from the bovine source, there was a minimal infection in one case, but in one case only, while in all the others, an acute and fatal tuberculosis resulted. Moreover, when injected into rabbits this type of bacillus produced a generalized tuberculosis in whatever dose it was exhibited. Chimpanzees proved highly susceptible to its action, whether the infection was made by inoculation or by ingestion. Other monkeys, pigs, and goats succumbed with equal certainty to the attacks of these bacilli.

The typical bacilli from human sources the commissioners divide into two groups: Group 1, containing bacilli which have the same cultural characters as the bacillus of the bovine type. This type of organism was found in, and examined from, fourteen different sources. Of these, however, it may be well to consider thirteen only as in Washington. Professor Koch objected to one of them on the ground that the sputum might have been contaminated through milk or butter taken by the patient. We know that all possible precautions were taken to prevent any contamination through

milk and that an attempt was made to eliminate the possibility of the entrance of the bacillus of bovine type along with butter. The inclusion of this case, however, is unnecessary for our argument and it may be eliminated at once from our statistics. Of these remaining thirteen cases, ten were associated with abdominal tuberculosis, and three with tuberculous cervical glands. In three of the ten abdominal cases it was found that the bacilli present in the lungs and cerebral meninges were of the same type and were as virulent as those separated from the mesenteric glands—that is, the remote lesions contained the typical "typus bovinus." These cases therefore may be said to be of the kind for which Professor Koch was searching in Germany. All the bacilli met with in this group, injected into, or ingested by, bovines, produce an acute tuberculosis. Similarly rabbits succumb when the infective material was introduced by either of the above channels and the organism is virulent for goats, pigs, monkeys, and chimpanzees. The dog is susceptible to this organism when it is introduced into the peritoneum. Rats inoculated react to it just as they do to the bacillus of bovine type, *i.e.* we have a wide distribution of the organism occurring without the production of any visible lesion. The virulence of this organism, though high, is not constant, and it, like the bacillus of the bovine type, is always found in the grades I, II, and III.*

In the second group of cases from human sources a bacillus of somewhat different character was isolated. This organism was found in forty cases examined. These forty cases were suffering from lesions varying greatly both in position and severity. in eleven of the cases there was pulmonary tuberculosis; in eight, abdominal tuberculosis; in eight others, joint tuberculosis; in six, the cervical glands were affected; in two, the bronchial glands; in one, the kidney; in another, the testicle; in another, the tuberculosis was generalized, while in two the lesions were unclassified. The bacillus from these cases differed somewhat in cultural characters from the type of bovine origin and also from the bacillus of Group I, also isolated from cases of human tuberculosis. It was more luxuriant in its growth, and, growing on potatoes, was often somewhat deeply pigmented. This bacillus, when injected in doses of 10 or even 50 milligrams, produces no general tuberculosis in calves. There is usually a lesion at the site of inoculation, very often surrounded by a firm, dense, capsule consisting of fibrous tissue and the tuberculous process seldom extends beyond the nearest lymphatic gland. In isolated cases there were a few scattered tubercles in the lungs and in the internal glands. In no case did death of a bovine animal result from the subcutaneous inoculation of cultures of this organism, and in the case of two viruses only was an emulsion productive of a progressive tuberculosis. In the rabbit the localization of the disease produced by the bacilli of this group is also usually well marked; this, however, is not constant, as in a few cases (four) an acute and generalized tuberculosis was produced in a certain proportion, about one-fourth of the rabbits injected. Although so slightly virulent for bovines and only slightly more so for rabbits, this organism, when fed or inoculated, is virulent for chimpanzees and other monkeys, and the lesions produced in these animals are in certain cases indistinguishable from those at first produced in rabbits and calves; later, however, they differ somewhat. In bovines and rabbits the lesions usually become retrogressive, while in the other animals the lesions are progressive and continue so until the death of the animal. It is interesting to notice that in dogs these viruses behave exactly as do bovine viruses. It should be observed that the organisms in each of these groups maintain a very remarkable stability as regards both morphological and cultural characters, even when passed through animals and after long and continuous cultivation.

I should here like to say a few words about Group III of the commission: A number of cases of tuberculosis of the human subject were found, the bacilli associated with which could not be fitted into either Group I or Group II, as above described. These are certainly not of the same type throughout, nor are they to be classified directly or under either one or other of above group headings, and, indeed, they have not sufficient in common to enable us to place them under one heading so that this "group" must be looked upon as simply a temporary "hold-all," into which are cast certain anomalous tubercle bacilli until we are able to study each individual more carefully. The one point of importance in connection with this "hotch-potch" is that we think we have some evidence that certain of the organisms contained therein may undergo some variation, not only in morphological characters, but in virulence, some of them appearing to be much less stable than are the bacilli classified in Groups I and II. This may come to be a matter of very considerable importance, but at present I must reserve any discussion on the matter, as the observations of the commission on this point are not yet completed.

The fact that Group I (*i.e.* the so-called typhus bovinus isolated from lesions in the human subject) has proved so large and important a group has to my mind far-reaching consequences. Dr. Eastwood has carried on certain experiments for our commission and has drawn up the classification above referred to of the various tubercle bacilli from bovine and human sources, grading the bacilli according to their growth on three media, broth, glycerin agar, and potato. These grades are by no means sharply defined; at certain points they gradually merge into each other. He insists, and, I think, insists very properly, that these grades are of service in so far that they enable him to indicate approximately the position of any particular strain by referring to it as belonging to a certain grade. Within each grade, he points out, there may be differences. The strains placed at the top of the grade growing less luxuriantly than those at the bottom.*

In the first grade are placed those tubercle bacilli which give a poor growth on the above three media. On broth the pellicle makes its appearance very slowly, is delicate, semitranslucent or slightly opaque and mottled with small, irregularly thickened areas, which are often white. The growth on glycerin agar is very slow, a thin grey haze on the surface being all that is to be seen at the end of five or six weeks. On potato the growth at the end of the same period consist usually only of a

*See Dr. Eastwood's classification given below.

*Dr. Cobbett and Dr. Stanley Griffith, two of the scientific investigators for the commission, also divide the strains they have examined into different grades, but their classification is scarcely so detailed as is that given by Dr. Eastwood.

few minute gray colonies or streaks. In this group are strains derived from seventeen cattle and from eight human beings—from the bronchial glands and spleen, from the knee-joint, and from lymphatic glands, mainly mesenteric, but some cervical. All of them are highly virulent.

In Grade II the bacilli grow better than those in Grade I, but the growth is still sparse. There is usually a thin growth, with a few thickened patches, which appears at a somewhat earlier period; it soon becomes moist and falls as a sediment to the bottom of the flask. On glycerin agar there is a small, grayish, moist, slightly raised growth, which, however, soon comes to a standstill. On potato the growth is sparse and nonpigmented, is apparent at a somewhat earlier period than in the case of Grade I and grows slightly more luxuriantly. In this group there are twelve strains of bacilli from bovine sources, three of them being the same as three of those found in Grade I. Five viruses from the mesenteric and cervical glands of the human subject were found in this group.

In Grade III the growth on all three media is somewhat more active both as regards time and amount, the pellicle is usually thicker throughout, the growth sinks and on both glycerin agar and potato there is a better growth and on the latter medium there may be slight pigmentation of the culture. Six strains of bovine origin were found in this group and eight of human origin, from the bronchial, cervical, or mesenteric glands, from the knee-joint and from the tuberculous tissue taken from cases of lupus. Cultures from strains in this grade correspond to certain cultures from the same strains found in Grades I and II.

In Grade IV the growth is still more vigorous and ultimately is much denser. It shows no tendency to become moist and to sediment in broth as do those in Grades II and III. On glycerin agar the growth becomes wrinkled, but does not become heaped up or warty. On potato the growth is certainly somewhat heaped up and is often slightly pigmented. In this group are found only two bacilli of bovine origin, while of human origin there are seventeen, some coming from the mesteric glands, some from the bronchial glands and spleen, some from the cervical glands, some from the lung, wrist and ankle-joint, the brain and its meninges.

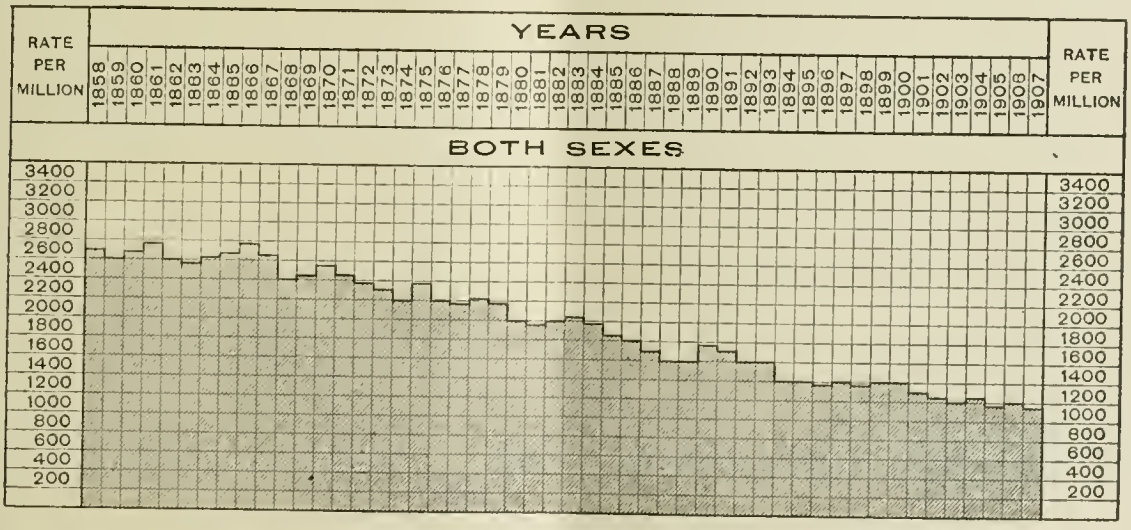
In Grade V. Dr. Eastwood puts all those growing luxuriantly on all three test media. On broth there is "rapid formation of thick, tough, wrinkled pellicle, with no tendency to sink. On glycerin agar, a layer which is usually both warty and wrinkled and denser than in Grade IV. On potato, rapid formation of a heaped-up, richly pigmented growth." In this group there are no tubercle bacilli of bovine origin, but we have twenty-five derived from human sources, from the tubercle of glands—mesenteric, cervical, axillary, and bronchial—and of joints, lung, liver, kidney, and testes.

It was found that the virulence of the strains in Grades I-III is markedly high, that of the strains in Grades IV and V very much lower and Dr. Eastwood came to the conclusion that, speaking generally, cultural character and virulence go together, the virulent bacillus, whether from bovine or from human source, growing less well on artificial media (other than serum) than those slightly virulent for cattle and rabbits. This parallelism, however, is by no means complete, as no gradation in virulence is found corresponding to the gradation which has been found in cultural characters, and many strains in Grade III have been found as highly virulent as the strains in Grade I, while going in the other direction many of the strains in Grade IV were as feebly virulent as were many of the least virulent in Grade V. Although, therefore, there is a very regular gradation as regards cultural characters, the transition in virulence is, on the whole, abrupt. The strains in Grade III vary very considerably as regards their cultural character, sometimes growing more abundantly, sometimes less, sometimes approaching Grade II, at others coming near Grade IV, and so on with other grades.

From these experiments it was gathered that, although a low vegetative activity on artificial and special test, culture media is associated with high virulence, and luxuriant growth of the bacillus on artificial media is associated with low virulence for cattle, and although many of the highly luxuriant growths coming from the human subject virulence for the bovine may be met with in all of the first four grades, but as the cultural luxuriance rises, it may be gradually, there appears to be a sudden drop in the virulence of the organism. Correlating all these facts the regular gradation of the cultural features, the general correspondence of virulence with a certain type of growth, but the marked departure from this correspondence in certain cases, and a certain amount of evidence of gradual transition as regards activity of growth and some though less evidence as to a more rapid transition of virulence, seem to point away from a division of tubercle bacilli into two hard and fast groups. I cannot here give the whole of the results obtained on this point; those who wish further information thereon might refer to Volume IV of the Appendix to the Second Interim Report of the Royal Commission on Tuberculosis.

In regard to the position taken up by Dr. Koch, a position no doubt the outcome of experience of tuberculosis in Germany, we consider then that we have obtained some evidence that mesenteric tubercle is the result of infection by tubercle bacilli contained in milk drawn from tuberculous cattle, and I, for one, am satisfied that I have seen such cases of infection which could be ascribed only to infection from bovine sources. As, however, this is a matter still under discussion it would not be advisable for me to say more than that further experiments have already been devised to test some of these points and that definite results appear to have been obtained in regard to some of them, and we hope that with the tremendous impetus that has been given to the question, in the first instance by Professor Koch, and again and again by him and those who have worked with him—and, if I may be allowed to say so, we are all working with him, even though we do not all agree with him on certain points—we may hope, from time to time, to gain fresh knowledge on this subject and ultimately base methods of prevision and treatment that may result in the stamping out of this disease. That such a hope is not extravagant and such an attainment outside the range of possibility or even probability may be gathered from a consideration of the tables given by the Registrar-General in his Seventeenth Annual Report of Births, Deaths, and Marriages in England and Wales in 1907, from which it will be seen that in England and Wales, owing to the various improvements in hygiene, in feeding, and in the general methods of life and treatment there

has been a steady and progressive fall in the death rate from the year 1858 down to the year 1907. Taking the period of forty years—1867-1906—, there has been a fall in the annual death rate per million living, at all ages, from 3,350 per million to 1,610 per million, a diminution of nearly 52 per cent. In fact were the same rate of fall to go on for another forty years, tuberculosis would have vanished from our midst, and, although this is not probable, we may hope that as a factor in the death rate of that period it may have become a comparatively unimportant, or almost negligible, quantity. In 1907 56,101 deaths were attributed to tuberculosis or "fewer, by 3,539, than the average number in the previous five years corrected for increase of population. Tuberculosis is therefore responsible for 10.7 per cent. of the mortality from all causes and for a death rate of 1,605 per million living, at all ages and of both sexes." Comparing this with the decennium, 1851-1860, we find that in that period the deaths from tuberculosis were in the proportion of 15.6 per cent. of the deaths from all causes, and corresponded to a rate of 3,457 per million of the mean population. It is interesting to note that the fall is much more marked in females than in males. In 1858, and for the next four or five years, the numbers were almost equal, about 3,300 per million, while in 1907 the rate per million had fallen to a little over 1,800 in males and a little over 1,400 in females. The phthisical cases during the same periods have fallen from about 2,620 to 1,175 in both sexes, and from 2,575 in males to 1,175 in 1907, and in females from 2,800 to about 930 in 1907 (see Chart).



Annual death-rate from phthisis, in England and Wales, per million at all ages.

What light may we throw on the subject of tuberculosis by a study of other diseases? In the case of pleuropneumonia contagiosa, we recognize at once that when we are allowed to isolate and slaughter infected animals, even those suspected to be suffering from the disease, we can make sure of stamping it out in time. Pleuropneumonia is not communicable to man, and few animals are affected by it as a "spontaneous" disease. Having a short incubation period and running a rapid course, it can be traced fairly rapidly to its source. If in the case of tuberculosis, even though the conditions are widely different in certain respects, we had only cattle to consider and the spread of tuberculosis to one another and the lower animals, we might hope, by adopting special methods of isolation, slaughtering and disinfection, to stamp out the disease though, no doubt, after a prolonged period of anxiety and suspense. We should have to remember that the disease, at first latent, might still be infective long before it becomes open and active, and that the infective material might have been disseminated all the more widely and surely because we were not able to recognize the disease with which it was associated.

Again, I understand that you in New York have been troubled, as have we, by a series of most incomprehensible outbreaks of typhoid fever. Quite recently it has been recognized that these are the result of infection by "typhoid carriers"—patients in whom the *Bacillus typhosus* has remained alive and active for years, multiplying at a great rate, and being discharged, perhaps at intervals, but over long periods—numbers of patients being infected as the result of coming into contact with these "carriers." How is it that these typhoid "carriers" have escaped detection for so long? Here we have an acute disease of which the incubation period is comparatively short, and where, therefore, the possibility of tracing infection should certainly be easy enough, but, as a matter of fact, these "carriers" have not been recognized until quite recently, though I must say that we now wonder what we have been doing with our eyes and other senses that we have not succeeded, long ere this, in tracing the connection of the "carriers" and the numerous mysterious outbreaks of typhoid fever. Now, if this holds good in the case of a disease in which cause is followed so quickly by manifest effect, is it to be wondered at that hitherto we have not been able to convince those (some of whom, perhaps, and not unnaturally, do not wish to be convinced) that tuberculosis in cattle is an infective disease, that this disease may remain latent for some time, and that even when we seem to have succeeded in getting rid of tuberculosis from a herd there may remain seeds or germs of infection in animals which, apparently healthy, may still act as "carriers." Moreover, knowing what we do of the tremendous infectivity of the typhoid bacillus for ordinary patients while on the immune patient it appears to have so little effect, who shall say that either cattle or human beings, though apparently only slightly affected may not be carriers of the infection of

tuberculosis primarily each to its own species, but perhaps, and even probably, in a lesser degree, to other species?

Let us consider the question from another point of view. In former days all cases of infective disease of whatever kind were placed indiscriminately in the general wards of the hospital. Then came a reaction, and all these cases were isolated and with most satisfactory results. Following this, however, came a second period of reaction, and we find in the medical wards of many of the hospitals of to-day that cases of enteric fever are there treated, often with the most satisfactory results. Does it follow from this that those who were isolated were overcareful? Certainly not. They were doing the best that was possible under the recognized conditions. When, however, the disease came to be better understood, the vehicles and channels of infection distinguished, and the means of prevention and disinfection determined, the trained nurse could be trusted to take adequate measures to prevent the carriage of infective material from one patient to another, and now we never have outbreaks of enteric fever in our wards. We still believe in the great infectivity of typhoid fever, and we relax none of our precautions against infection, but, having determined what precautions are necessary, we can carry them out all the more thoroughly because we are not hindered by unnecessary "top-hamper." We have determined that the great factor in the prevention of disease is the destruction of the infective material that comes from the patient, thus preventing it from gaining access to others. We have determined the channels by which this infective material leaves the primary patient. We have also traced the method of existence outside the body and, finally, have determined the channels and the vehicles by which the secondary patient is infected.

Leprosy, of all the diseases due to an infective agent (and for the present we will accept it that it is an infective disease), appears to be the most distinctly and definitely confined to the human subject. It is a disease, therefore, which should be most easily controlled by isolation. As Dr. Newsholme pointed out, the other evening, wherever segregation has been resorted to, leprosy has gradually disappeared, it being found necessary to take no other precautions in order to stamp it out. In countries in which no such measures have been adopted, leprosy continued rampant, but as soon as segregation was put into force (as in Norway), the number of cases began to diminish, and this diminution has gone on steadily down to the present time. Robin Island, off Capetown, one of the segregation camps for South Africa, has proved of enormous value to South Africa in collecting patients from centers of infection. Leprosy, no doubt, is less infective than tuberculosis, but its incubation period is probably considerably longer, tuberculosis, in this respect occupying an intermediate position between typhoid fever and leprosy. May we learn something from this as to our treatment of consumptive patients? I think we may.

Just one more example. If we study the history of rabies (hydrophobia), we find that here we have a case that may help us in planning our warfare against tuberculosis. Last year I wished to demonstrate to my class in Cambridge the Negri bodies in the central nervous system of a rabid dog. What was my astonishment but delight to find, after searching Great Britain high and low, that we hadn't a case of hydrophobia in the country. Finally I had to write to Dr. Anna Williams, asking her for some smear preparation and sections in which I might demonstrate these bodies. These she very kindly forwarded to me, and thereby laid me under a debt of gratitude, as I was thus enabled to show these organisms to my class. Some time ago, hydrophobia, or rabies, was as prevalent among the dogs of our island as it was in the United States. Mr. Walter Long, late president of our local government board—in spite of the great outcry from so-called humanitarians, and against the wishes of those who maintain that rabies in dogs was the result of high temperature, want of water, of irritation, of everything but an organism, but who maintained that to muzzle a dog was the surest way of giving hydrophobia—enforced a national muzzling order, with the result that in about three years rabies had disappeared and with it the need for any institute for the treatment of cases of hydrophobia in man, developed in Great Britain. We may safely say that had a single rabid dog been left among us it would probably have proved a center for another outbreak as soon as the conditions for the transmission and distribution of infective material again became favorable.

In the case of tuberculosis, as with rabies, we must, of course, take every possible precaution to prevent the transmission of infective material from man to man, but must we not at the same time make certain of getting rid of that comparatively small, but certainly not negligible, danger of infection of our child population having its source in tuberculosis of bovine origin. Many years ago Professor Osler demonstrated, in connection with the outbreak of smallpox in Montreal, that a small unvaccinated remnant may keep smallpox alive for a considerable time, this remnant proving a center from which the disease may spread along all favorable channels. It serves as a center of infection and necessarily, therefore, a source of danger, even to the vaccinated, of whom a small percentage may not be absolutely protected, against a large dose of the infective virus. I maintain, therefore, and in this I fancy I am now on the side of the majority of those who have investigated this subject, that tuberculosis of the bovine, even though it may account for but 5 per cent. of the cases of tuberculosis in the human subject, should be more vigorously attacked and strenuously harried. It is the more important that we should undertake this in that in some ways there are fewer obstacles to its elimination than in the case of tuberculosis transmissible from the human subject, and, in any case, if this type of the disease can be eliminated from the children of the nations there will be so many fewer centers of infection and some, at least, of these children will grow up stronger and healthier, and better able than they are at present to stand the attack of other forms of disease.

For the last week or ten days we have all heard much of different methods of fighting the white plague. We have listened to the discussion of many able papers, strong statements have been made and, if some of these statements are true, others will have to be taken with considerable reserve. We have been assured by one set of workers that all we need do to stamp out tuberculosis is to obtain careful isolation; by others that the real panaceas are fresh air, ventilation and good food. By some our public buildings, our streets, our milk, our but-

ter are placed under a ban; and who shall say that these propagandists have not right on their side as, under certain circumstances, we know that the tubercle bacillus may lurk in many or all of these. While acknowledging the importance of these details, and certainly in the long run we must attend to them, would it not be well to lay down certain general principles and then try to put these principles into practice, varying them only according to the necessity of individual cases? We are surely come to that stage of knowledge at which it is necessary to insist that tuberculosis is an infective disease and that, without the presence and aid of the tubercle bacillus there can be no tuberculosis. Has not the time come for us to lay under a ban such phrases as the "so-called infectivity of phthisis," "what some describe as the main etiological factor in tuberculosis," and the like? Whatever part the resistance of the tissues of the individual may play in warding off phthisis there can now be no doubt that we may accept with confidence the dictum, "no tubercle bacillus, no tubercle." That being accepted, I maintain that wherever we find the tubercle bacillus, whether you can prove its virulence at the time you find it or not, you must treat it as though it were then and there capable of acting as a virulent infective agent. At present there can be equally little doubt that we have tubercle bacilli, different strains of which vary enormously in their virulence. Some of us think that we have evidence of the variation of the virulence, even in the same strain when placed under artificial conditions. We are not, however, at present acquainted with the conditions under which modifications of virulence go on. These modifications may take place in the host, and, though they may extend over a very long period, there seems to be a possibility that an organism may gradually acquire increased virulence, even in the same host, as in the case of plague, and we should as soon think of failing to take steps to eliminate nonmalignant plague as we should think of placing children side by side with mild cases of scarlet fever, diphtheria, or smallpox. We know that the nonvirulent tubercle bacilli may, in the first instance, produce but a local lesion but we never know when the resistance of the tissues may be so lowered that they will allow of their general invasion even by this apparently not very virulent tubercle bacillus.

Workers in overcrowded areas where ventilation is bad and nutrition low, where crowds are packed together in squalid hovels during what should be their period of rest, will tell you that overcrowding is the main cause of tuberculosis, and that the only preventive measure is strict isolation of those most affected. For those little or not affected already they advise destruction of rookeries and opening up to the light and air of heaven of such dwellings as are allowed to remain. They are in the right. On the other hand, another investigator will tell us that the population he has studied is housed in well lighted and fairly well ventilated houses, that when they are at home the conditions of life, if not ideal, are certainly far from bad; but, during the day, while at work, they are compelled to breathe a dry, dusty atmosphere in a badly ventilated room. He will tell you that overcrowding at home has no bearing on the spread of phthisis, and that phthisis is very largely a trade disease. He also recommends isolation, ventilation of workshops, and, of course, better nutrition. He is right as far as the day conditions are concerned, but do his facts go against the conclusion of our other observer? Each man may bring forward statistics to prove his own particular case, and it is because both are right, in matters of general principle, that the statistics agree; but it is because each insists too much on certain details that they disagree as to the interpretation of their facts and figures. One man claims that we could put a stop to tuberculosis tomorrow if we could isolate in hospitals all the open and advanced cases of the disease, and he tells us that where sanatorium treatment has been tried it has done little to lower the death rate from tubrculosis and still less to diminish the case rate; and he will put forward statistics in support of his contention. Are we justified in saying that because we see no immediate improvement none has taken place? May it not be contended that every early case that has been checked, that has been prevented from becoming an advanced or open case, is one center of infection cure and must therefore, in time, have a marked influence on the statistical aspect of the question?

The aim of those interested in preventive medicine is to "corral" the tubercle bacillus, and I fancy that nowadays most of us are indifferent as to how this is effected so long as we succeed in doing it thoroughly. As in the case of typhoid carriers and lepers we have to devise some practical and practicable method of dealing with each set of cases, and even with each case as it arises, and it is for this reason that the work of the tuberculosis dispensaries has been attended with such a large measure of success. The medical men and their assistants in these dispensaries, from one case are able to trace others. They come across cases of tuberculosis in all stages of development and among all sorts and conditions of men; they weigh up the possibilities of treatment in various individual circumstances, and, having adopted the treatment that seemed best to meet the conditions and necessities of the case, they are able to provide a resting place in which the poor, wornout worker can end his days in comparative peace and comfort, without being a danger to his fellows. They are able to train the patient suffering from incipient phthisis in cleanly and in effective and safe methods of disposing of his sputa, etc. So that should all efforts at cure be unavailing the patient, even in the most infective stages of his disease, by the care he exerts, is able to reduce the danger of infection from himself to others to a minimum. From all this it is evident that we must make use of those means which come most readily to hand and which, at the same time, appear to meet most closely the exigencies of any special case.

If we could in this way banish from our midst the various strains of tuberculosis from human sources we should be doing much to diminish the death rate from tuberculosis. But should we get rid of tuberculosis so long as we allow the disease to exist in the lower animals, as, for example, in the bovine? Here, again, must we not do everything that is practicable to eliminate it as an infective disease of these animals? It must always be a source of danger, even though it be assumed, which I do not, for a moment, admit that the bovine type of tubercle bacillus is not so infective for the human subject as is the human type, and accounts for but a small number of cases.

In the case of children (and on this point observ-

ers, including those working on the German Imperial Commission, seem to agree), we have a definite and frequent affection of the alimentary canal and of these cases a certain proportion are undoubtedly of bovine origin. As my colleague, Dr. Cobbett, pointed out, of the cases of fatal tuberculosis in children, "investigated by the German and English Commissions, about one-third were found to be due to the bovine type of bacillus. The cases were largely selected as being of alimentary origin, and are all too few for the purpose of forming an estimate, but they form the only material available. Now, cases of death from tuberculosis under five years form about 20 per cent. of all fatal cases of tuberculosis, and if we may estimate that somewhere about one-third of these are bovine infections it follows that a little less than 7 per cent., or one-fourteenth of all deaths from tuberculosis are due to bovine infection. This estimate is a very rough one, but it is near enough to show that bovine infections in man are fairly common. The estimate probably errs in being too large because the cases on which it is based were mainly selected as examples of infection through the alimentary canal. On the other hand, it may possibly be too small, if modification of one type into another takes place, because phthisis being a chronic disease, it is conceivable that some cases may be caused by the bovine bacillus, which, becoming gradually modified into the human type, is no longer distinguishable from the latter when the case comes under investigation. But of this there is no evidence. The bovine bacilli found in man are, in every respect, like those found in the cow, and are just as virulent for that species."

Going a step further, we may say that every tuberculous cow is a potential or actual center of infection for other bovines, and, as we have seen, though perhaps in a lesser degree, for the young child and, quite possibly in a lesser degree still, for the young adult. How are we to get rid of these centers of infection? A counsel of perfection would be to examine and test with tuberculin all animals, whether suspect or not, to destroy all that react, place all that remain unaffected in disinfected, well ventilated and lighted sheds, and repeat the process until all tuberculous cattle are eliminated. Such a procedure is, of course, impracticable and, as Bang has pointed out, is not necessary. He has succeeded, by careful isolation of the infected animals, by the elimination of animals that are in an advanced or open condition of tuberculosis, and by sterilizing the milk fed to young animals, in gradually freeing from tuberculosis valuable herds of cattle and thereby in giving us a guide for our own work. By all means let us educate the stockbreeder and the dairy farmer to a proper appreciation of the value of tuberculin; let us look forward to the time when the tuberculin tests will be applied as a matter of course whenever there is the slightest suspicion of the presence of tuberculosis in an animal or herd, but let us not wait for this before doing something to try to rid our herds of the more dangerous cases of tuberculosis.

All medical officers of health and veterinarians will receive with open arms and welcome the recommendation of the recent congress at Washington that a beginning should be made by eliminating cows suffering from tuberculosis of the udder from all dairy supplies. The importance of this is obvious to any one who has given a moment's consideration of the question, or has examined the sediment from half a dozen specimens of milk drawn from such cases. This, however, is the first step merely, and the addition of cases of advanced or open tuberculosis to the list of cattle to be condemned would be an eminently wise and satisfactory addition. It may be that we shall have to accept this as a first installment of what we now aim at, and it appears possible that it may be advisable to confine our attention, in the first instance, to this special point. It would certainly be well worth our while to cut out these very active centers of infection, centers corresponding to the human patient who suffers from advanced phthisis, a patient whom we desire to keep under as close control as possible but whom we keep isolated in a hospital instead of pole-axing him. I believe that in time those who now resent interference with any but the manifestly diseased cattle will come to see not only the propriety but the economy of getting rid of cattle tuberculous in any degree. That, however, is not yet, and in the meantime it is well that we should aim at the attainable.

SPECIAL FEATURES IN THE SYMPTOMATOLOGY AND PATHOLOGY OF ANEMIA OF THE CENTRAL NERVOUS SYSTEM.*

By SAMUEL LEOPOLD, M.D.,

PHILADELPHIA.

After the excellent contributions of Minnich, Lichtheim, and Nonne in Germany, Putnam, Taylor, Burr, Lloyd, Dana, Spiller, and others in this country, Russell, Batten, and Collier in England, and Bastianelli in Italy, there seems little that can be added to the clinical and pathological picture in anemia of the spinal cord. For the most part these observers have developed the clinical and pathological changes incident to this disease. A few have endeavored to establish a distinct clinical entity, while others have concerned themselves with the disease in relation to the pseudosystemic diseases. Moreover, the rôle played by the anemia, the influence of special toxic agents, as well as the part played by the blood-vessels, have been thoroughly discussed in the last decade.

The general clinical symptoms of paresthesias, weakness, ataxia, and spasticity are too well known for me to enter into a discussion of them. The spinal changes consist in symmetrical areas of sclerosis, involving most frequently the posterior and lateral tracts. The lower cervical and upper thoracic segments show the most extensive degeneration. The blood-vessels are congested, and their walls sometimes show hyaline degeneration. The perivascular spaces contain leucocytes and granular material. Besides the neuroglia proliferation, rarefaction of the fibers and may spaces are noted. Where they have disappeared sometimes small hemorrhages are seen. The cells in the gray matter show usually pigmentation.

Certain clinical features are worthy of mention in our series, six of which were studied clinically and pathologically and two only clinically. The onset of this disease is usually gradual, occurring over many months. In Case VI the peculiar feature of sudden onset was noted, the clinical symptoms of weakness and paresthesia developed in twenty-four hours. In Case I we noted the presence of a sharp,

*From the Department of Neuropathology of the University of Pennsylvania.

almost girdle-like zone of anesthesia, reaching to the umbilicus. This symptom, according to Nonne, is uncommon. It may complicate the diagnosis as it did in one of Nonne's cases, in which a diagnosis of tumor was made. Sometimes the character of the pain is puzzling and Dr. Spiller tells me of a case in which the pain was located in the back at the level of the third thoracic vertebra, and radiated from this situation. The diagnosis of tumor of the spinal cord and anemia, the patient having 3,000,000 red blood corpuscles, was difficult.

Another striking feature in the study of these cases has been the variable character of the symptoms in the different cases. This variableness is also to be noted in the cord changes. Sometimes only the posterior columns are involved. This was observed by Lloyd in the case which he published, and the microscopical sections of which I have again studied. Sometimes the process is seen in both the posterior and lateral tracts; again it may be noted as a diffuse sclerosis of the entire cord. Thus it is quite apparent why these cases may be diagnosed as tabes, disseminated sclerosis, myelitis, and tumor. Nonne has had the opportunity of studying some of the earlier forms of the disease and reports isolated foci of sclerosis affecting various levels of the cord. These apparently have no special predilection for any one system of fibers. From these findings, together with the varying character of the clinical symptoms, in a recent contribution he concludes that this disease is not systemic but focal in character. I fully share this recent view of Nonne, as the material at my disposal (six cases) fully justifies his conclusions. It is interesting to note in passing that he formerly believed in the systemic character of this process, and that only in his last contribution to this subject he returns to the theory advanced some years ago by Leyden and others.

Sometimes, as Spiller remarks, the paresthesia and ataxia may persist for many years with little change in the cord; and, on the other hand, the intensity of the alterations may be much greater than the clinical symptoms suggest. This peculiarity has also been noted by most observers in the character and relation of the anemia to the disease process.

Two unpublished cases, one of Dr. Spiller, the other of Dr. Mills, illustrate this. In Dr. Spiller's case, S. P., female, the physical examination showed a spastic gait, ataxia, ankle clonus on the right side, Babinski's reflex distinct on each side. Sensation for touch and pain was diminished in the lower limbs, almost normal in the upper limbs. There was no involvement of the cranial nerves. The blood count showed 8,160 white blood corpuscles and 5,090,000 red blood corpuscles.

Dr. Mills' case, M. P., was a female, aged thirty-two, with a history of pain in the back and legs but with no physical symptoms except some exaggeration of the knee jerks; no disturbances of sensation, no ataxia or spacity; the blood count showed as low as 2,240,000 red blood cells, 46 per cent. of hemoglobin, and 16,000 white blood corpuscles.

While not definitely proved, the theory of a toxic agent associated with the anemic state seems to be most plausible. In this connection it is interesting to note the incidence of tuberculosis. In two out of six of our cases which came to necropsy, tuberculous lesions were found in the viscera. In a review of the cases reported I find about the proportion of one to seven.

To what extent is the brain involved? In our series of cases we note the presence of convergent strabismus, right facial palsy, inequality of the pupils, and slow response to light. Russell also reports unilateral facial paralysis, and in another case paresis and ataxia of the larynx. Bulbar symptoms have been reported by Putnam, Taylor, and others, while Weisenburg and McConnell have reported a case with double optic neuritis. This is interesting, for the question has arisen whether anemia could produce optic neuritis, some holding that it only produced optic atrophy.

The mental state has been variously pictured, most observers stating that the patient is dull and inattentive. They frequently state that physical examination is unsatisfactory, owing to the dullness of the patient. Nonne reports clouding of the mental state from somnolency to delirium. The majority of my cases showed apathy; two cases were reported as emotional and one as hysterical. Toward the end of the disease in some of the cases delirium and confusion occurred, and in others stupor, but it is questionable if these later states played a part in the anemic picture, owing to the association of a terminal infection. An interesting side light is thrown upon this subject by the clinical studies of Pickett, Grawitz, and Siemerling in various types of anemia. Pickett reported five cases in which the composite picture showed shallow confusion with impairment of the ideas of time and place, with fabrication and relating imaginary experiences, not unlike Korsakow's syndrome. Illusions as well as hallucinations and persecutory delusions were common. Grawitz emphasized the apathy, unfeelingness, and melancholia in some, while in others there were stages varying from excitement and delirium to mania. Siemerling most recently has endeavored to establish a definite clinical picture in this condition and compares it to the state arising in the course of infections and intoxications.

Our cases show that the spinal cord symptoms predominate over the cerebral, and no definite mental syndrome is seen. A review of the literature corroborates these findings, though one must not overlook the fact that this phase of the subject may not have been given sufficient attention.

From the pathological studies of the brain in anemia, the changes found in the brain might account for the train of symptoms described by Pickett and others. Recent experimental studies of Orr and Rows have shown swelling of the perivascular lymph spaces, loss of contour of the cells, chromatolysis, and congestion of the vessels. In my studies of the cortex a similar picture was noted. The pathological changes found in the spinal cord in most of our cases correspond to the usual findings. In Case III, however, we found the unusual feature of involvement of only the left crossed pyramidal tract, the posterior columns were symmetrically and widely degenerated indicating that the process was of some duration. The extent of the lesions reached in two of our cases to the medulla, and one of these could be traced by the Weigert method to its upper border. The involvement included the pyramidal and direct cerebellar tracts. Mott, Russell, Spiller, and others have found the destructive lesions as high as the mid-region of the pons, and Mott and Russell have been able to trace the degeneration by the Marchi method as far as the cortex.

Case I.—H. S., in the service of Dr. Spiller, male, aged fifty-five, had no venereal history; used alcohol moderately. The family and previous medical history was negative. About two years before ad-

mission he noticed a creepy sensation and feeling of pain in the right leg, and shortly after the left leg became affected. One year later his gait became unsteady and his feet felt numb. Four months later he could not use his lower limbs and a few months before admission he began to have dribbling after urination.

Physical examination: He could rotate inward the lower limbs very slightly at the thigh; otherwise the limbs were paralyzed. He could not even move his toes. Patellar tendon reflex was entirely absent, even on reinforcement on right side; very faint on left side. Achilles tendon reflex was nearly normal on each side; Babinski's on both sides. Plantar reflex was greatly exaggerated on each side, especially the left. Irritation of the left sole caused the left knee to be flexed three or four times, and contractions occurred in most of the muscles in the lower limb. The cremasteric reflex was preserved on each side. Sensation for touch, pain, and temperature was entirely lost in lower limbs. Sensation for touch, pain, and temperature was diminished over front of trunk below the nipple line. Sensation was lost in irregular areas over the thighs. The movements of the upper limbs were free; the grasp of each hand was normal.

Examination three weeks later showed complete motor paralysis in lower extremities. Sensation was lost to a point at the level of the umbilicus. A band of hyperesthesia was noted above this extending three inches in width. The patellar tendon reflexes were absent; Babinski's reflex present. The grasp was weaker and patient complained of numbness in hands.

Blood examination revealed 11,000 white blood corpuscles, 45 per cent. hemoglobin, 2,580,000 red blood corpuscles.

Microscopical examination: The changes in the spinal cord showed extensive and symmetrical sclerosis of the posterior and lateral tracts from the lumbar to the cervical region. In the lumbar segments the sclerosis was "V" shaped in the posterior columns. The periphery and a portion of the root entrance zone were free. The crossed pyramidal tracts were involved on both sides; only the right direct pyramidal tract was involved. In the thoracic and cervical segments the sclerosis was more extensive, but similar in distribution.

Clinical summary: There was no history of syphilis. The family and previous medical history was negative. The illness began two years before admission with paresthesia and weakness in lower extremities. There was loss of bladder and rectal control. The patellar reflexes were absent; Babinski's present. Motor paralysis was complete in the lower extremities. Sensation was lost to the level of the umbilicus. There was hyperesthesia in a band three inches in width above this area. A diagnosis of myelitis was made.

Pathological diagnosis: Combined sclerosis from anemia. The changes in the spinal cord were symmetrical and involved the posterior and lateral tracts from the lumbar to the cervical region.

Case II.—I. H., in the service of Dr. Mills, aged sixty-eight, male, colored, had a negative family and previous medical history. The present illness began two years before admission with a feeling of numbness and tingling in the legs. This trouble increased with weakness until he was unable to work. About the same time his hands and arms became weak and numb. For the past three months he had had shooting pains in the legs.

Physical examination: The pupils were equal, reacted to light and accommodation. He performed all the movements of the eyes except convergence; attempts at convergence brought inward the right eye at times, the left remaining in the median line. There was no paralysis of the fifth, seventh, or other cranial nerves. In the upper extremities the movements were equally weak on both sides. The limbs were somewhat spastic. Ataxia was shown by the finger-to-nose test. There was very marked atrophy of the shoulder and arm muscles. These muscles were the seat of fibrillary tremors. There was some wasting of the ulna and interosseus groups. The biceps and triceps reflexes present but not increased.

Lower extremities: The limbs were weak and ataxia was marked in both legs. The patellar tendon reflexes were increased on the right side and preserved on the left. Ankle clonus was absent. The muscles of the left leg and thigh were more atrophied than on the right. Fibrillary tremors were noted in the atrophied muscles.

Sensation: Response to touch, pain, and temperature were correct in all parts of the face, trunk, and upper extremities. In the lower extremities there was complete loss of tactile sensation in all portions of the thigh, legs, and feet. Hypalgesic areas were found in various portions of the thighs and legs. Thermic sense was undisturbed. Sense of position seemed completely lost in the left and greatly impaired in the right. The mental condition was apparently fair until about ten days before death when there were signs of mental confusion. Just before death he had convulsions.

Necropsy protocol: Catarrhal pneumonia with cheesy encapsulated foci of tuberculosis; brown atrophy of heart; infection of the right kidney and ureter.

Microscopical report of spinal cord: In the lumbar region the areas of degeneration were symmetrical in the posterior and lateral columns. A fair number of fibers in the periphery and continguous to the septum had escaped in the posterior columns, also the root entrance and cornu comissural zones were intact. The crossed pyramidal tracts were symmetrically involved. The direct pyramidal tracts were not involved. In the thoracic region the involvement was more extensive and still showed its symmetrical arrangement. In the cervical region the process was most extensive; only the root entrance zone and cornu commissural zones were free, and here many rarefied fibers were noted. The lateral columns were extensively degenerated. The sclerosis involved the crossed pyramidal, direct cerebellar, and Gowers' tracts. The direct pyramidal tracts were only slightly involved. The pathological changes were those of anemia. Small hemorrhages and slight round cell infiltration of the perivascular spaces were noted. Many new capillaries were seen throughout the sclerosed areas. The cells in the anterior horns showed considerable pigmentation. The medulla and pons showed no changes. Section taken from the cerebral cortex showed marked distension and congestion of the vessels in the meninges and throughout the interior. Their perivascular spaces contained considerable granular material. The ganglion cells were in some instances swollen; chromatolysis was noted, and the nuclei were misplaced.

Clinical summary: Male, aged sixty-eight, had loss of power and paresthesia in lower limbs, extending over two years; ataxia; spasticity in all four limbs. Increased patellar reflex on right side, Ba-

binski's positive. Tactile sensation was lost in lower limbs. There were marked muscular atrophy in upper limbs, and mental confusion nine days before death.

Microscopical diagnosis: Combined sclerosis. Sclerosis was symmetrical and extensive, involving the posterior and lateral columns. In the cortex the chief changes were congestion, cloudy swelling, and chromatolysis.

Case III.—J. W., in the service of Dr. Dercum, aged sixty-one, teamster, admitted specific venereal infection. The clinical examination of this patient was very meager. The present illness began two months previously with weakness and loss of control of lower limbs. Examination showed ataxia, no muscular atrophy, no disturbances of sensation; right facial weakness. The mental state was dull, and at times the patient was delirious and talkative. Death occurred three weeks later. The clinical diagnosis was specific myelitis.

Pathological report: In the lumbar region no degeneration was noted. In the thoracic segments the posterior columns were symmetrically involved; the crossed pyramidal tract was involved only on the left side, a few of the fibers of the posterolateral tract were also involved. In the cervical segments the sclerosis was most extensive, the posterior columns were symmetrically involved; the crossed pyramidal tract and a few fibers of the posterolateral tract were involved only on the left side. The medulla at the decussation and above showed no involvement of the pyramidal tract, but showed sclerosis in the lateral tract. The pathological changes present showed no evidence of specific inflammation, but the presence of the areas of sclerosis, the vacuolated areas (*Lucckenfelder*), and vascular changes resembled anemia of the spinal cord. Pathological diagnosis: Combined sclerosis.

Case IV.—J. C., in the service of Drs. Mills and Spiller, aged sixty-two, iron worker, denied syphilis. The family and previous medical history was negative. Present illness: Two years previous to his admission he had phlebitis in both legs and was ill for three months. One year later he became weak in the lower limbs. Following a fall he was unable to move his left leg and soon after lost the power in the right leg. Three weeks later he regained enough power in his legs to move about with the aid of a cane. At time of admission he was unable to walk, and complained of numbness in the hands and legs.

Physical examination: Pupils reacted to light and convergence. There was no weakness of facial muscles, nor muscular disturbance. The tongue was protruded in the median line. No muscular atrophy was noted in the upper extremities. The biceps and triceps tendon reflexes were prompt on each side. The sensation to touch and pain was normal. In the lower extremities the left knee was enlarged and a little warmer to palpation than the surrounding parts. The left leg was partially flexed on the thigh and there was resistance to passive movement. Muscular atrophy was not pronounced. Voluntary movement of the toes and ankles was about normal. The patellar tendon reflex on the left side was exaggerated, while the right was only slightly so. There was no ankle clonus. The Achilles tendon reflex was diminished on each side; Babinski's positive on each side. Tactile sensation seemed to be entirely lost in both lower limbs below the knee and was markedly impaired in the right thigh and about normal in the left. The pain sense was apparently lost in the same areas as the tactile sensation; it was diminished in the right thigh and nearly normal in the left. There was no impairment of sensation to touch or pain over the abdomen or the lower part of the back. The patient had a feeling of constriction passing directly through the umbilicus. There was decided rigidity in the lower limbs to passive motion.

Diagnosis: Lesion of the spinal cord in the lower thoracic region.

Necropsy protocol: The lungs showed tuberculous deposits at both apices. There was chronic interstitial nephritis and also present a large amount of yellowish fat which suggested pernicious anemia.

Microscopical examination: In the lumbar segment the posterior columns were symmetrically involved, but not so extensively as in the thoracic or cervical areas. A triangular area and oval area around the septum were involved as well as the root entrance zone and cornu commissural zone. The direct pyramidal tracts were not involved; the crossed pyramidal tracts were involved on both sides, but more so on the right. The lesions were those of sclerous and vacuolated areas, together with perivascular infiltration and new formation of capillaries. The thoracic segments showed a symmetrical involvement of the posterior and lateral columns more extensive than in the lumbar, but less than in the cervical. Gowers' tract and the anterolateral ground bundle showed little sclerosis but showed the vacuolated areas. The direct pyramidal tract was involved only on the right side. In the cervical segments the lesions were most extensive. The columns of Goll were entirely destroyed except for a peripheral zone. The columns of Burdach were less involved and the root entrance zone and cornu commissural zone were preserved. The scleroses, vacuolation, and perivascular infiltration showed the same characteristics as in the other segments.

Summary: Male, aged sixty-two, developed illness during a period of two years. The illness began with weakness and paresthesia in the lower limbs and girdle sense. Improvement was followed by remission; weakness and spasticity, increased patellar reflexes, Achilles reflex diminished no ankle clonus, Babinski's reflex was positive on both sides. Tactile and pain sensation was lost in both lower limbs in the same areas; there was no disturbance of cranial nerves.

Macroscopic examination showed tuberculosis of the lungs and kidneys and appearance of anemia in the other organs.

Microscopical examination: Symmetrical and extensive sclerosis and vacuolation most marked in the posterior columns and lateral columns of the cervical and thoracic segments. Direct pyramidal tract was not involved on the lumbar segment. Crossed pyramidal tracts were more involved on the right side. Changes were those of anemia. Microscopical diagnosis was combined sclerosis.

Case V.—M. S., female, in the service of Dr. Spiller, had no specific history, but was an alcoholic three years before. Family and previous medical history was negative. The present illness began after standing for the entire morning. She noticed that her legs were weak and she was able to walk only with support. She complained of numbness and tingling in the limbs.

Physical examination: The pupils reacted to light and accommodation; the former was not so prompt. The extraocular movements were normal as was

sensation in the face. She drew up the corners of the mouth well on each side, closed her eyes and wrinkled the forehead well. The tongue was protruded in the median line. Upper extremities: The grasp of the hands was poor. The upper limbs were not wasted. Biceps tendon reflexes were exaggerated on each side. There were no sensory disturbances. Voluntary movements and resistance to passive motion were normal. Lower extremities: There was marked paralysis in the lower limbs. She could flex the thigh slightly at the hip and knee. Resistance to passive movements was feeble. Patellar tendon reflexes were markedly exaggerated on each side. Patellar clonus was persistent on each side; ankle clonus on each side. Babinski's reflex was not obtainable. The muscles of each calf and each peroneal nerve were sensitive to pressure. No atrophy was noted and sensation was normal.

Diagnosis: Specific myelitis.

Microscopical examination: No evidence of specific changes was noted. In the lumbar segment the anterior and lateral columns were normal except for a few spaces where fibers had dropped out (*Lueckenfelder*). In the posterior columns the areas of sclerosis and rarefaction were small and seen as small islands surrounded by normal fibers. The fibers contiguous to the septum were intact. Normal fibers were found in the periphery, the root entrance zone, and bordering the gray commissure. In the areas of sclerosis were found small vessels with thickened walls; their lumina were distended with blood. In the thoracic segment the islands of sclerosis in the posterior columns were more numerous, the areas between them showing the *Lueckenfelder*. In this section there is also involvement of the lateral tracts and direct pyramidal tracts, characterized by *Lueckenfelder* and sclerosis. In the cervical segment the sclerosis in the posterior columns is more extensive than in the other segments and has the form of a triangle. Around the root entrance zone the *Lueckenfelder* was noted, a similar dropping out of fibers was seen in the lateral and anterior fields of white matter. The crossed pyramidal tracts are not so markedly involved as in the thoracic portion. The cells in the gray matter showed considerable pigmentation; the Nissl bodies were broken into fine granules and the nuclei were pushed to the side. In the medulla above the decussation the *Lueckenfelder* was noted in the lateral tracts. No changes were detected in the pons. In the brain the blood-vessels showed congestion, the cells were markedly pigmented, the nucleus in some had been pushed to the side, the cell bodies were swollen. With the Nissl stain some of the Betz cells showed loss of staining power.

Summary: Sudden onset with weakness and paresis in the lower limbs; patellar tendon reflexes were exaggerated on each side, also patellar and ankle clonus. Paresthesia in lower limbs. The duration of the illness was three months. Clinical diagnosis was specific myelitis. The lesions were symmetrical and most marked in the lower cervical and upper thoracic areas. The early character of the process was noted by the small areas of sclerosis, though the changes were far more extensive than one would expect to find in an illness of three months' duration. The lesions were found as low as the lumbar region and as high as the medulla. The changes in the brain cortex corresponded to the findings of other observers in their studies of anemic states; namely, congestion, pigmentation, chromatolysis, and changes in size and shape of the cells.

Pathological diagnosis: Combined sclerosis.

Case VI.—M. D., in the service of Dr. Pickett, female, aged forty-eight, weaver, was an alcoholic at times. Previous medical and family history was negative. Two years ago the patient stated that she was standing on the street waiting for a car and her feet became frosted. From that time on they felt numb. After about a year she began to have pains in the lower extremities and an increasing weakness. At present she complains of numbness, pain, and loss of power in the lower limbs. The pupils were slightly unequal, the left being a little larger than the right; they reacted to light, accommodation, and convergence. The extraocular movements were normal. Face wrinkled equally well on both sides. The tongue was protruded in the median line. The patient could not stand or walk. Upper extremities: The grip was not very strong but about equal on each side. The biceps tendon reflex responded slightly. No atrophy of any muscle was noted. Lower extremities: The patellar tendon reflexes were absent on both sides, even on reinforcement; also the Achilles tendon reflex. Babinski's sign was doubtful. The left leg was smaller than the right. Sensation to touch was diminished in the lower extremities. There were no areas of anesthesia and no loss or diminution of pain sense. The lower limbs were contracted, all voluntary power was lost and passive extension almost impossible. The mental state was emotional.

Microscopical examination: Lumbar segments: In the posterior columns the sclerosis was triangular in shape with its base at the periphery. The fibers around the gray commissure were intact as well as those forming the root entrance zone and oral field at the septum. The lateral portion of the white matter was involved, the remainder of the white matter was normal. In the thoracic region the posterior columns were extensively involved; the area was triangular in shape. The crossed and direct pyramidal and posterolateral tracts were extensively and symmetrically involved. In the cervical regions there was complete sclerosis of the posterior columns except for a few fibers of the root entrance zone. The sclerosis in the lateral and anterior white matter was marked. *Lueckenfelder* were found in the pyramidal tracts and in the lateral tract. In the medulla at its upper portion a similar involvement was found in the pyramidal and direct cerebellar tracts. No changes were found in the pons. In the cortex the cells showed pigmentation, chromatolysis, and swelling. The nuclei had migrated to the side. The blood-vessels were distended and congested and in one portion a small area of thrombus, hemorrhage, and softening was noted. In the cord and especially in the posterior columns numerous small vessels were seen with sclerosed walls and distended lumina. In a few areas small hemorrhages were noted. The cells in the gray matter showed pigmentation and some chromatolysis.

Summary: In Case VI there were weakness and paresthesia in the legs. Left pupil was larger than the right. There was no cranial nerve involvement; absence of all reflexes. Sensation to touch was diminished in the lower extremities. Duration of the illness was about two and a half years.

Microscopical examination: The areas of degeneration were extensive and symmetrical, extending from the lumbar region to the upper border of the medulla. The most extensive involvement was in the lower cervical and upper thoracic areas. The chief features were the marked degree of degenera-

tion and the extent to which the brain was affected.

Pathological diagnosis: Combined sclerosis.

I wish to take this opportunity to thank Dr. Spiller for the privilege of reporting these cases and for his kindly criticisms.

THE SPLASHING SOUND OF THE STOMACH.

By J. W. WEINSTEIN, M.D.,

NEW YORK.

In our routine examinations of the abdominal viscera we often elicit a splashing sound over the stomach area. In most of the cases the patient is not aware of its existence. At times the patient will notice that on tapping his stomach a splashing sound is produced. He, however, is not perturbed by its existence, but comes to the doctor merely in quest of on explanation of the phenomenon. More rarely he feels the splashing with the changing of the position of his body. His stomach feels like a bag of water suspended within the abdominal cavity, which changes its position according to the laws of gravitation. The patient is greatly annoyed and even distressed by it. It is the object of this paper to discuss the meaning, the significance and the diagnostic possibilities of the splashing phenomenon.

How is the splashing sound produced? Any body of some size having yielding walls and containing fluid or semi-fluid contents and air or gas, on being tapped, causes a displacement of the relative positions of the liquid and the gas, which is necessarily accompanied by a splashing sound. The stomach fulfills all of these conditions, as it mostly contains in the state of digestion besides the semifluid food some air or gas. The origin of the air or gases of the stomach is partly derived from being swallowed from the air or being ingested with the food, partly due to fermentation within the stomach. Another part bubbles upwards into the stomach from the intestines through the patent pylorus. The stomach is, therefore, a viscus which is ideally adapted for the production of the splashing sound, and we can, therefore, elicit a splashing sound in most of stomachs, irrespective of age or sex. The writer makes this statement after having tested the splashing on every patient that came under his observation for the last few years. Children are no exception to the rule.

Why, then, can't we produce the splashing sound in all cases? Tense abdominal muscles do not transmit the tapping blow of the hand to the stomach, and hence no splashing is produced. A very thick abdominal wall will, for obvious reasons, interfere with the production of the splashing sound. A stomach in a state of distention after a heavy meal will again interfere with the production of the splashing sound. Again, the presence of mere food without any air or gases in the stomach is another hindrance to the production of the splashing sound. The presence, therefore, of the splashing sound in any stomach means merely the presence of fluid or semifluid contents plus air or gases in the stomach. I have heard some clinicians designating any stomach where splashing can be produced as one of atony. I consider it erroneous. I have noticed the splashing sound in perfectly healthy children time and again. Should it, however, be elicited at all times with the greatest ease over a fairly extensive area of the abdominal space, it may occasionally point to a loss of tone or atony of the stomach. It may point to such a diagnosis, but not necessarily mean it. And we have no right to diagnose it as such unless we have used other means of diagnosis and have established the existence of a mild degree of motor insufficiency in the stomach. It is then that the diagnosis of atony of the stomach is fixed. The best way to elicit the splashing sound is to have the patient in a recumbent position with the thighs flexed, relaxing himself as much as possible, and then suddenly to tap the stomach region. The amount of force required varies mainly with the thicknesss of the abdominal walls. In some cases the lightest stroking with the middle finger will bring it forth in a most satisfactory manner. In others again quite a forcible blow with all the fingers combined is required to get it out.

I said before that the splashing sound was a perfectly normal phenomenon. There are, however, two other factors to be taken into consideration in order to make this rule universal, namely, the time and the place, *i. e.* it is a normal phenomenon, provided it is produced at the proper time and at the proper place, and it is here where the diagnostic possibilities come in.

Suppose a patient presents himself in the morning with a stomach history. He happens to have an empty stomach, not having ingested anything that morning. We put him down on a couch and splash his stomach. A splashing sound is obtained. Here it is pathological, for any stomach should be empty seven hours after a full meal. It is evident that the stomach of this patient contains something, while it should be empty. What are the substances that are likely to be present in a jejune stomach? It must be either food or gastric juice, more rarely some regurgitated duodenal contents, some swallowed saliva and mucus. We next proceed to introduce a stomach tube and siphon out the contents. If the contents prove to be food, it will signify to have been left from the previous supper, and that the stomach did not succeed to empty itself in the lapse of time during night. Whenever a stomach cannot empty itself after a full-sized meal in seven hours, it is a case where the motor powers of the stomach are impaired or motor insufficiency. Should the contents prove to be pure gastric juice without any admixture of food at all, it will mean that the stomach is secreting gastric juice all the time, even when no food is introduced into the stomach. A condition like this is known in gastrology as continuous gastric flow, gastrosuccorrhæ, or Reichmann's disease.

Regurgitated duodenal contents is recognized by its yellow-greenish color. It is never profuse. A few drachms at the utmost. The characteristics of saliva are so well known that nobody need have any difficulty in recognizing it. It is not often present in the jejune stomach, and at best is present only in very small quantity. I wish, however, to add right here that the smallest quantity of liquid contents in the stomach, say one-half drachm, is likely to give a splashing sound, and it is absolutely impossible even for the most experienced to judge from the splashing sound as to the quantity of contents in the stomach. The stomach tube alone, with painstaking removal of all the material, can settle this.

The utilization of the splashing sound of the stomach, when produced at a time that the stomach ought to be empty, becomes apparent. It has served in my hands time and again to the greatest advantage. On the very day of writing these lines it has cleared up for me a case of pyloric obstruction, and I do not think it to be amiss to illustrate how I did it.

A patient came to the Vanderbilt Clinic giving an ordinary dyspeptic history with vomiting. The patient had been sick for about six weeks. In going over the abdomen I noticed a marked splashing sound over the stomach region. This was at 4 P. M. I questioned the patient as to the time of his last meal, and he assured me that he had not had anything since 6 A. M. that day. This made an interval of ten hours. Any stomach with a normal motility must be empty after a full-sized meal in seven hours. It became, therefore, evident to me that this patient was suffering with motor insufficiency. I introduced a stomach tube and secured, without any difficulty, about 1½ quarts of a very fluid substance, of a very acid odor, containing all kinds of foodstuffs in fine subdivision. A stomach containing 1½ quarts of contents ten hours after a meal, with a history of stomach trouble for six weeks, means a pyloric obstruction. I could not feel any pylorus; nor were peristaltic movements visible.

I cannot refrain from citing another case even at the risk of being too cumbersome. I was called to see F. S., female, aged 20, in July, 1908. Chief complaint was palpitation of the heart. The patient had been confined to bed for four weeks without any improvement. I learned at the bedside that the patient had been treated for the past five to six years by a variety of doctors, among whom numbered some of the best clinicians in the city. The patient informed me that the diagnosis of most of the men was heart disease. Others thought it was nervousness and anemia. The chief complaint was palpitation of the heart. Her heart action was not very regular and rather tumultuous. I could not hear any murmur, and I concluded that it was either a case of cardiac lesion without a murmur or a cardiac neurosis. The patient improved somewhat, and I sent her away to the country, where she stayed for five weeks. She came back somewhat improved, but by no means well. One evening about 7 P. M. the patient came into my office complaining of the same old symptoms, and telling me that she felt very ill. On making the routine examination I noticed a marked splashing over the stomach area. I questioned the patient as to the time of her last meal, and was informed that she had had nothing the whole day except a cup of milk in the morning. My attention was drawn at once to her stomach. After a couple of test meals, I arrived at a positive diagnosis of atony of the stomach. I instituted treatment for this condition, and her improvement was almost phenomenal. The patient has been in the best of health ever since without having any recourse to any medical treatment.

Having disposed of the diagnostic features of the splashing sound as to the time of its production, I will now proceed to another phase of its diagnostic possibilities, namely, the space over which a splashing sound may be produced. By making out the area over which it is produced we are enabled to determine the size and position of the stomach. The percussion here must be light with one finger only, and is adapted for favorable cases only, such as have thin abdominal walls. We can thus make out by splashing the upper border and also the lower border of the stomach. I do not mean that the whole outline of the stomach can be made out by splashing, since the stomach, when full of food, is almost vertical in its position, with a slight slanting from left to right, the greater part of the fundus of the stomach being located under the left dome of the diaphragm. It is, therefore, only the lower right segment, that part that is not covered by the costal arch, that is exposed to splashing. Should the upper border of splashing prove to be near the ensiform cartilage or slightly below it, and the lower border one or more fingers above the navel, the stomach is normal in size and position. Should the upper border be again near the ensiform, which is its normal upper level, and the lower border below the navel, the stomach is dilated. Should the lower border prove to be one or more fingers below the navel and the upper border down correspondingly below its normal upper level, the case is evidently one of gastroptosis.

The splashing sound is of inestimable value after lavage, especially in those cases of atony of the stomach where we want to give the stomach a rest after the lavage, and where our object would be entirely defeated by leaving food behind. I cannot emphasize too strongly how hard a task it is to empty a stomach completely. My stomach tube in lavage is always supplied with a stiff rubber bulb having a great suction power. This bulb is employed both to stir up the contents within the stomach and as an aspirator to siphon out the contents. The stomach tube is invariably introduced at different levels and suction each time employed, and still, with all these precautions, and after all these painstaking manipulations, after using quarts of water flowing out perfectly clean, I invariably, after the operation, put the patient on a couch and try the splashing sound, and, to my chagrin, more often than not, it is easily obtained. I have the patient then roll on the stomach, change his position, shake him well up, and then on introducing the stomach tube again—a good deal of fermented food comes forth. I have on several occasions in obstinate cases of this character suspected a stomach with two chambers—the hour-glass stomach. Such did not prove to be the case, however. The great value of the splashing sound in these cases is obvious.

We will now turn our attention to that class of cases where the patient himself is conscious of the splashing sound. The stomach hangs in the abdominal cavity like a bag full of water, and changes its position according to the laws of gravitation. Any movement of the body is accompanied by splashing and very unpleasant sensations to the patient. Such stomachs are usually atonic; not in all the cases, however. A stomach is atonic in the true sense only, when its motor powers are impaired. And the real criterion of the integrity of the motor powers of the stomach is its ability to propel a good-sized meal in seven hours without leaving any residue within the stomach. I have got at present two typical cases of this order under observation, one in a young man and the other in a young woman, where the motor powers of the stomach functionate perfectly normally. The loss of tone in these cases seem to be in the attachments of the stomach. These attachments are chiefly the cardiac end, which is continuous with the esophagus and is attached to the diaphragm, and the pyloric end, which is continuous with the duodenum, and is attached to the spinal column. The peritoneal folds, such as the lesser omentum and the Ligam. phrenico-gastricum, are very frail, and offer very little fixation. The hepatoduodenal ligament, however, is a much stronger peritoneal fold. Another very important element in the fixation of the stomach is the support it receives from the juxtaposition of the neighboring viscera. A relaxed abdominal wall is, therefore, one of the

contributing factors in the class of cases under consideration.

The diagnosis of these cases is very easily made, as the splashing is very pronounced, especially when the patient changes his position on the examining table, we can distinctly hear the splash. We are enabled very easily in such cases to move the contents of the stomach from one side of the abdomen to the other with our hands. Lavage is of decided value in such cases. The in and outflow of the water seems to serve as an elegant tonic and invigorating remedy to the weakened points of fixation of the stomach. A properly fitted abdominal support is an efficient adjuvant remedy.

Sources of Error in the Splashing Sound.—The inexperienced, in making out the size and position of the stomach by means of the splashing sound, will be very prone to diagnose dilated stomachs, where none exist, the reason being that in a large number of cases a percussion blow in any part of the abdominal cavity will transmit a wave to the stomach with an accompanying splash. To safeguard against this error we must notice that the splash is produced right under the finger and not at a distance of it. It takes some experience to learn it. A second source of error is a splashing in the colon or small intestine. It is very rarely that we can elicit a splashing sound in the intestine, but we must keep it in mind. I very nearly made a mistake recently. A young woman complained of constipation and cramps with which she had been suffering for about a year. On examination strong peristaltic movements were noticed. Splashing was elicited over almost the whole abdomen. One was very much tempted to diagnose it as pyloric obstruction with marked dilatation of the stomach. The splashing seemed to be right under the finger all over. The peristaltic movements, however, seemed to be much below the normal position of the pylorus. The stomach was inflated with gas and found rather small. It was evident that the obstruction and the splashing were confined to the intestines and not the stomach.

61 East One Hundred and Seventh Street.

SUCCESSFUL TREATMENT OF A CASE OF SPECIFIC SALPINGITIS WITH GONOCOCCUS VACCINE.

By ALBERT L. TUTTLE, M.D.,

MILFORD, CONN.

On August 21, 1909, the case came under my care. Four days previously the husband consulted me for a suspicious discharge. He made stout denial as to probable cause, but I treated him according to my suspicions. When called to see the wife I found the expected sequence. I need say nothing further to suggest the etiology.

Mrs. B., aet. 20, married, mother of one child, born June 27, '09. Labor and puerperium were normal and without complication. She recovered her usual health and strength, if we consider that the pains and weakness of child-bed are a departure from health, and, true to the instincts of motherhood, she nursed her offspring. That an infection had occurred there was no doubt, as to just when I did not insist on knowing. Aug. 17 she "began to feel sick," but could assign no definite symptoms. Aug. 19, there began to be painful urination and a purulent discharge apparently from the vagina. Aug. 21 I was called, as above stated, and found patient with a temperature of 103°, and on examination evidence of urethritis and vaginitis and a thick, purulent discharge escaping from the uterus. No pain or tenderness was complained of in the region of either fallopian tube. Aug. 24 urethritis and vaginitis were subsiding under treatment, temperature normal, but still discharge from uterus. Aug. 25, temperature 102°, pain and tenderness severe in the region of the right tube and radiating down both thighs, enlargement and tenderness of the right tube, left tube not involved. There had been no chill, so I was informed. Treatment: Ferri et quinin, opiates for pain, antiphlogistine, hot antiseptic douches, etc. Aug. 26, slight relief from pain, less tenderness, temperature 100°. Aug. 27, pain much less, temperature 98.6°; free discharge from os showed good drainage. Sept. 4, much pain and increased tenderness referable to the right tube, temperature rising to 104°, probably due to obstructed drainage. Got busy with douches, poultices, etc., and good drainage was soon re-established with abatement of fever and other symptoms, and for a few days there seemed to be slight improvement, but not sufficient to disguise the perspective of a future course long drawn out, of remissions and exacerbations, destructive of every ambition that should make life worth living for the patient; destructive of the disposition, if not the health of her attendants; and, sad fate, of the reputation of the attending physician. In the hope of avoiding all of these contingencies, I expressed the opinion that desirable results could not be obtained except by an operation; and I asked for a consultation. I called Dr. J. W. Wright of Bridgeport. This was Sept. 10. After examination he expressed himself as fully in accord with my diagnosis and prognosis. Examination at this time showed the right tube much enlarged and filled with pus; neither the left tube nor the uterus showed any involvement.

He advised delay for a few days, at least, and careful observation, although an operation no doubt would ultimately be the only rational course promising success. Suggestions as to treatment in the meantime included some simple iron preparation, internally and thorough attention to use of laxatives; continue douches and flaxseed poultices, and add the use of compound ichthyol suppositories per vaginam.

Nothing worthy of note occurred during the succeeding two weeks, except gradual tendency to improvement, although there did appear a slight involvement of the left tube, and, on Sept. 19 violent pains, rise of temperature to 102°, abdominal distention, and other things suggestive of invasion of all the abdominal viscera and, peradventure, the thorax. Palpation quieted my fears, and investigation otherwise proved an intercurrent acute indigestion, due to indiscretion as to an article of diet. This condition quickly cleared up, and the temperature returned to and remained at normal. Pain and tenderness of right tube and, to a slight degree, of the left, was still present, but not very severe, the discharge continuing in considerable quantity. The patient was all this while confined to her bed, except occasionally she was able to be up for a few minutes.

At about this time my attention was directed to the use of antigonococcic serum and the results claimed. It occurred to me that this might be a good test case, and I sought information from all available sources, yet failed to find any satisfactory report of a case parallel to mine. I waxed

not strenuous, scarce sanguine of success, if even harm might not result, but being assured that the latter could not happen, I frankly laid before the family the result of my investigation, stating that to be the extent of my own knowledge. I think my frankness appealed to them, for they were more than willing to try it, in the hope, though vague, of a recovery without operation. I secured a package of four bulbs, 20,000,000 bacteria, each, of gonococcus vaccine, and on Sept. 25 at 10 A. M., made the first injection, near the lower border of the scapula, of .5 c.c., or about 5,000,000 bacteria. At 4 P. M. the same day, the patient complained of marked increase of tenderness and pain in the region of the right tube and radiating down the thigh. When I called at 8 P. M. her temperature was 99.8° (it was normal before the injection). There was also a decided increase in the discharge. This increase of the symptoms, of course, constituted the "reaction" naturally following the injection. I was informed the next day that at 11 P. M. the symptoms of reaction had passed, that the patient felt much stronger and better, and had slept all night until 8 A. M., the most natural and restful sleep since she had been sick.

On Sept. 26 there occurred another slight attack of indigestion, which having passed, at 5:30 P. M. I gave the second injection, 1 c.c. Sept. 27, reaction in evidence, but very slight, except for a much more abundant discharge. At 11 A. M. injected the whole contents of one bulb, 20,000,000 bacteria. Called again at 8 P. M. and was informed that during the afternoon there had been pains in the region of both tubes, radiating to the uterus and down the thighs, latter but slight temperature, 99.6°, pulse 100. This was the reaction, but it was passing, and she was beginning to "feel very comfortable." Sept. 28, feeling better than the preceding day, but the discharge was profuse, and urination was somewhat painful, no injection that day. Sept. 29, discharge greatly diminished, painful urination subsiding. Injection of 20,000,000 bacteria. Sept. 30, some reaction, but not severe, increase of discharge and slight pains as before. Oct. 1, reaction passed. Oct. 2, marked improvement as to all symptoms, strength and appetite much better, discharge scarcely shows on the napkins, though some was noticeable in the douches, but hardly more than a trace. Injection of 20,000,000 bacteria, fourth and last bulb of the first package. Oct. 3, considerable pain of reaction previous night and still present but less, discharge also had increased, but again diminished. Otherwise she feels much better, skin and countenance are greatly improved in appearance and expression, the color is more nearly that of health, and the skin feels softer and more natural to the touch.

Although decided improvement had apparently resulted from the injections, I was still inclined to be skeptical as to its permanency, and did not continue the injections for a time, but watched if there might be continued progress in the right direction without them. Gradual improvement did seem to continue during the succeeding two weeks. Douches, suppositories, and general treatment was kept up as also they were during the serum injections. Oct. 10 and 11 the patient was dressed and brought down stairs, the 12 she walked down. Perhaps there was overexertion, perhaps there was other cause, but on Oct. 14 there was a return of the pain and tenderness of the right tube, and, to a lesser degree, of the left, an increase of the discharge and the temperature rose to 102.5°. Thinking, perhaps, the time had come for more radical measures, I advised the Bridgeport Hospital, with a probable operation by Dr. J. W. Wright, or a further trial of the serum. I rather wished for the latter course, but was not strenuous to advise.

I went over all the evidence, *pro and con,* then told the family the responsibility would be theirs to decide which they had the most faith in. They could take until the next morning and let me know. Oct. 15, temperature normal and all the other symptoms abated, and the verdict was: "more serum." Oct. 16, there was at this time some tenderness and discharge, but not very much of either. Injected 1 c.c. of the vaccine. Each of the three bulbs of this package contained 2 c.c., number of bacteria not stated. For six consecutive days I injected half the contents of a bulb each day, observing strict aseptic precautions, both in administering the dose and in protecting that left in the bulb to be used the next day, considering the risk of contamination or deterioration of the latter so slight that I might venture to take it. Perhaps it was the kind Providence that watches over children and fools that prevented serious consequences.

During these injections there was no manifestation of reaction nor after any subsequent ones. From now on there was gradual and uninterrupted improvement each day, all tenderness disappearing, and, after Oct. 18 no discharge could be detected, either on the napkins or in the douches. The suppositories had been discontinued for several days, and there was no tenderness of the tubes on vaginal examination; only there remained a slight thickening of the right tube, this was also noticeable at the time of the last examination, which was Oct. 29.

Apparently a cure had been effected and the patient was gaining steadily in strength and general health. But, *certiorem facere,* I ordered the third package. It not occurring to me to state how many million bacteria per dose, I received four tubes, 1 c.c., 100,000,000 bacteria each.

I ventured to inject .5 c.c. the first dose, nothing whatever happened, so I used the rest of that bulb the next day, and thereafter, on alternate days, 1 c.c. of 100,000,000 bacteria each, the last one being administered on Oct. 27.

Neither at that time nor since have I been able to detect any remaining symptoms of the disease, other than the thickening of the right tube, as stated. At 5 P.M., Nov. 11, I called at her house and found Mrs. B—— just returned from a tramp in the woods, still in long coat and soft hat, and appearing, as she claimed to feel, not fatigued, but refreshed and invigorated by the exercise.

With pardonable pride she brought in her baby, who had been left outside in her carriage, for me to see how she was thriving. Also, I was informed that the first menses since Mrs. B——'s accouchement had put in an appearance the day before, and that it was normal in every respect and painless.

Early in the course of the disease the mammary secretion failed, and the baby had to be put on the bottle.

Oftentimes we can get more birds with weapons of our longest and most familiar acquaintance, if perchance they may be of rather antiquated type. I used my common sense and best judgment, such as they were, and did not avail myself of the advantages of the opsonic index. Whoever reads this will have his own conclusions, good, bad or

indifferent, so I need scarcely add any, but this much I will say: that I believe a complete and permanent cure of a typical and by no means mild case of specific pyosalpingitis has been effected by the use of three stock packages of gonococcus vaccine, the time of treatment being about one month.

A SURGICAL ACCIDENT NECESSITATING INTESTINAL RESECTION.

By EUGENE H. EISING, M.D.,

NEW YORK.

ADJUNCT SURGEON, LEBANON HOSPITAL; ASSISTANT ADJUNCT SURGEON, MOUNT SINAI HOSPITAL.

The following case presents some unusual features from both the surgical and the medicolegal aspects of more than passing interest.

Dr. X. requested me to see with him a patient whom he had just curetted. The patient was a young woman, married one year; she had not menstruated for the past two months, and for that reason considered herself pregnant. While engaged in her household affairs she fell and soon thereafter began to have pains in the lower part of the abdomen, one hour later she began to bleed. The bleeding had continued two days, when Dr. X. was called to see her. He at first prescribed medicine, but inasmuch as the bleeding continued, after two days he arranged to empty the uterus by curettage.

The doctor told me over the 'phone in great alarm, that just as he had considered the curettage completed he found that his instrument had passed upward indefinitely, meeting no resistance, and that upon withdrawing it, to his dismay, found that with it he brought down a considerable length of intestine. He consulted for a moment with his anesthetist, who advised him to replace the intestine carefully into the abdomen. This he did as well as he could under the anxiety of the moment, packed the vagina with gauze, and hastened to the 'phone. On the strength of this history I considered any delay fatal and urged him to place his patient in a hospital where, if necessary, any surgical procedure could be undertaken under the best environment. Upon my suggestion, therefore, he brought the patient to a sanatorium in the neighborhood.

Within four hours of the accident I had examined the patient. Her condition was apparently good and in no way betrayed the serious nature of the intra-abdominal condition. The pulse was slow and regular, respirations were normal, and there was no elevation of temperature. Her color was good, she was talkative, and could not realize why she had been transported to a sanatorium. The vaginal examination revealed slight bleeding from the cervix. No instrumental examination was made. There was practically no abdominal tenderness except what one might naturally expect after a curettage. In other words, the indication for an exploratory incision was to be found in the statements of the doctor and not in the patient's condition. Realizing the importance of the next few hours and the gravity entailed in awaiting the advent of indicative symptoms I decided to explore at once.

Upon opening the abdominal cavity the condition soon revealed itself. The uterus was slightly enlarged and the fundus showed a small laceration about 1¼ inches in length. This was hastily closed and bleeding checked. Concealed by loops of normal intestine a mass of gray collapsed small intestine was discovered in the cul-de-sac of Douglas to the left side. This piece of intestine had been torn entirely free from its mesenteric moorings. It was two feet in length, empty and collapsed, and of a color that I had never seen before assumed by intestine and evidently due to ischemia. There was neither fluid nor feces in the peritoneal cavity excepting for a certain amount of blood. The intestine was ileum, its distal end being 2½ feet from the ileocecal junction.

My first thought was to implant the ends of the intestine in the wound, making an artificial anus, but the high site of such a resulting fistula determined me to do an anastomosis. This latter procedure was quickly done with the aid of the Murphy button and the wound was closed with a small drain. The patient's recovery was uneventful, the button was passed on the ninth day.

18 East Sixtieth Street.

Simplified Method of Estimation of the Fats in Milk.—A. L. Rapisarda has modified the method of estimating the fats in milk, so as to make the apparatus compact enough to be carried in a moderate sized box. He uses the method of Gaertner, eliminating centrifugation, and using milk heated to 70° C. He tested milk of goats, cows, and asses, as well as human milk. The test must be carried out for an hour and a half to be reliable. All that is necessary is a simple apparatus, consisting of a thermometer, a graduated pipette, two Gaertner tubes, and bottles containing the sulphuric acid and amylic alcohol. Having got the analysis of the fats, it is not difficult to estimate the other constituents of the milk.—*Rivista di Clinica Pediatrica.*

Has the Fat of Foods an Effect on the Mother's Milk?—Armando Malagodi finds a great difference in opinion as to the effect on the fats of human milk corresponding with changes and increase of the fats in ingested foods. After experiments made by him on patients in the obstetric clinic at Bologna, the milk having been carefully analyzed, he gives his conclusions. In only one of his cases was there any increase in the amount of fat in the milk with an increase of fats in the foods. A decrease of fat in the food produced a decrease of fats in the milk. But there was an important change in the quality of the milk, which could be noted in the color and the density of the fat in the milk. This will account for some of the attacks of dyspepsia in infants with a change in the food of the mother, or the taking of unaccustomed foods.—*Rivista di Clinica Pediatrica.*

Operations for Suppurating Sinuses.—C. A. Buklin, in studying a case in which the bone comprising the wall between the frontal and ethmoidal sinus was exfoliated into the nose, arrived at the following conclusion: (1) In this case the wall having sloughed out, owing to ethmoid inflammation, the frontal and ethmoidal sinuses become one large cavity, which completely cured the disease. (2) Successful operations have been performed on the ethmoidal and frontal sinuses in an effort to imitate their suppurative process. Hartmann's forceps were used by a method described in the article. The cures resulting from the uniting of the two sinuses are always permanent and without annoying complications. One cut usually suffices to make the opening large enough, but the latter may be enlarged to meet the requirements. Suppuration in the frontal sinus usually originates in the ethmoidal sinus. (3) Should the inflammatory thickening, or other cause, make the operation with the Hartmann forceps impossible or too dangerous, the "sphenoidal chisel" may be used: this is more rapid and certain, but more dangerous than the first-named operation. The two operations are commended as being less dangerous than the exterior operation on the ethmoidal and frontal sinuses. If the postoperative progress is not good, potassium iodide in increasing doses should be given. In discussing the operation on the sphenoidal sinus, Buklin describes the "sphenoidal chisel" and the method of using it. This procedure is an improvement on the usual sphenoidal operation in that the instrument is placed before there is any bleeding, and, after placing it, it is not necessary to look into the nose. He says that the chisel offers the best, quickest, and safest method of performing the operation of opening the sphenoidal sinus without any annoying complication. In these cases the failure of cure indicates the administration of the iodides.—*Archiv für Laryngologie.*

THE TACTICAL MANAGEMENT OF ARMY MEDICAL RELIEF UNITS IN WAR.

THE February issue of the *Military Surgeon* contains an article by Surgeon Munson of the Army, on the utility of map problems in the education of army medical officers, which throws an interesting side light upon one of the multifarious functions of the army surgeon. While, of course, the practice of physic and surgery among the sick and wounded is a fundamental duty of the medical man in or out of the military service, the profession and public generally have come to realize that, in its actual humanitarian results among troops, preventive medicine possesses even greater importance, and that "A far greater blessing he secures who stops the coming ill, than he who cures."

The article above referred to, however,treats of the important administrative and executive duties required of army surgeons with fighting troops in time of war. The subject is one which is, and has been, curiously neglected; for while it represents a phase of purely business activity which is wholly extramedical, yet this phase is an essential antecedent in bringing about conditions through which medical and surgical relief work after battles is made efficient, and needless suffering prevented. It is clear that no amount of preparation and of resources is of any practical humanitarian value until the patient, the doctor, and the hospital equipment have been brought together. To accomplish this to best advantage in armies in the field requires a thorough knowledge of military organization, conditions, and methods; and since this duty is one which is specifically laid upon the Medical Department and its performance and the responsibility for results are thus not to be evaded, it follows that the subject is one which must be duly studied by medical officers of the army and of the militia as one of the accessory but essential branches of their medicomilitary education. It is quite true that the subject is one which does not appeal to the scientific side of the earnest professional worker, but the great humanitarian benefits which flow from its intelligent application in war are more than sufficient reason for its study and understanding in time of peace. When war comes, the patriotic but untrained medical officers can acquire this necessary medicomilitary information only through the humiliation which results from personal mistakes and with unnecessary agonies and deaths in the soldiers with whose welfare they are charged.

With the steadily increasing number of combatants in modern battles and the marvelous improvements in the instruments and appliances for human destruction, comes a greater necessity for regarding the Medical Department not as a collection of individual humanitarian units, but as a great military machine or instrument of precision, directed by the brain rather than the hands of the Chief Surgeon. Under our present army organization, the Chief Surgeon of a field army would have about 8,000 medical officers and hospital corps men under him for orders, hospitals aggregating about 8,000 beds dependent on him for equipment and supplies, and anything up to some 15,000 sick and wounded looking to him for relief. Without due preliminary training no doctor could be competent to administer a position of such vast responsibility and develop its complicated, special machinery, any more than the busy ophthalmologist or gynecologist would be competent to step from his office into that of a great transportation or manufacturing concern employing many thousand men, install its outfit, and direct the operating forces.

The picture which we have drawn for us of Field Marshal Oyama in the recent Russo-Japanese war is that of a quiet little man, himself far from the fighting, moving his almost half million soliders by telegraphic orders, like pawns along their sixty-mile battle line. With him stood his chief surgeon, fully informed and able to answer all questions as to his own department, following the tactical movements on the map and suitably altering, with the approval of his commander, the disposition of the sanitary troops in the more prompt and efficient relief of suffering and the freedom of the fighting force from the incubus of the wounded. What the chief surgeon thus did in an administrative way was of ten thousand times as much benefit to his country and to humanity as he could ever have possibly accomplished through his efforts as an individual surgeon in an operating room. The admirable results which he achieved for his department were gained only through the efficient administration of a practical business organization dependent on intimate knowledge acquired by special study.

In our next war we shall require relatively few such chief surgeons, but they must be men whose intimate military insight and forceful executive capacity are such as can be sorely tried without being found wanting. But we shall need a vast number of medical men in the less conspicuous but none the less important positions with the fighting troops, to whom a working knowledge of military and medical organization and methods is of absolutely essential importance. An abundance of the best medical talent in the country would be available for the treatment of wounded in the hospitals in the rear, and shortage would exist only in respect to trained medical officers fully conversant with the accepted methods of getting the wounded there. This duty must fall largely upon the medical officers of our national militia, who greatly outnumber the medical officers of the regular army and largely

compose the framework upon which a medical organization for war would have to be created. To such, especially, due consideration of the points raised in the suggestive article above mentioned is earnestly commended.

THE INFECTIVITY OF TYPHUS FEVER FOR MONKEYS AND ITS MODE OF TRANSMISSION.

Experiments have been carried on recently with regard to tabardillo or Mexican typhus fever by John F. Anderson, director of the Hygienic Laboratory, and Joseph Goldberger, both of the U. S. Public Health and Marine Hospital Service. The latest investigations in this direction have had as their object the discovery of the means whereby this disease is transmitted. Some of these studies were conducted in Mexico City, but on account of the illness of one of the investigators the remainder of the work was performed in Washington, whither the experimental animals, monkeys, with the exception of one animal, were transported. In the second note published by the investigators they recorded the experimental production of fever after the inoculation with blood from cases of human tabardillo in two species of monkeys, one a female *Macacus rhesus*, and the other a male *Cebus capucinus*. The researches, on account of which has been published in Public Health Reports, Feb. 18, 1910, were continued in order to determine whether the fever thus produced was tabardillo, and the endeavor was made to arrive at this result by testing the immunity of these monkeys by again inoculating them with virulent blood. These investigations were successful, but in order to prove the point absolutely further experiments were undertaken which were also successful.

As for the mode of transmission of the disease to man, the peculiarities of the epidemiology of tabardillo suggested to the authors the existence of an intermediary host, as they had previously practically convinced themselves that the malady was not contagious in the ordinary sense of the word. Accordingly, infection by insects was regarded as a solution of the transmission problem. Fleas and bedbugs were dismissed as probable infective agents for very sufficient reasons. Experiments were conducted with body lice and it was found that the lice used for the experiment could be kept alive only at a temperature of 14° to 20° C. The influence of temperature on the longevity of the louse seemed to the observer strikingly significant in relation to the apparently singular limitation of the disease to the Mexican plateau, *i.e.* to places having an altitude of not less than 1,500 to 1,800 meters, and its complete absence from lower altitudes, and in relation to its seasonal prevalence. The conclusions reached were: (1) At least two species of monkeys, *Macacus rhesus* and *Cebus capucinus*, are susceptible to direct inoculation with blood from human cases of tabardillo. (2) One attack of the disease in the monkey produced by blood inoculation directly from man induces a definite immunity to a subsequent inoculation with virulent blood. (3) The blood from human cases of tabardillo is infective on at least the eighth day of the disease. (4) The blood from the monkey, *Macacus rhesus*, is infective by passage to a second monkey of the same species on at least the fifth and sixth days of the disease. (5) Diluted blood serum from a human case, when passed through a Berkefeld filter failed when inoculated into a monkey to produce the disease. (6) The blood of a monkey of the species *Macacus rhesus* is infective, though its infectivity is somewhat attenuated, to a second monkey of the same species. (7) The disease is not conveyed by families, as such, nor is it contagious in the ordinary sense of the word. (8) The epidemiological facts of the disease point unmistakably to an insect intermediary; and the authors believe that their observations point strongly to the body louse as this insect. (9) They think the evidence is strong enough to demand that prophylactic sanitary measures directed against this disease should take into consideration that insect.

Almost every day appears to bring evidence that in the transmission of a disease of an infective nature insects are to a greater or lesser extent responsible for its conveyance. Therefore, in the attempt to stamp out such diseases, the modern motto is seek the insect, and either exterminate the species or protect the human race from its attacks.

APLASTIC PERNICIOUS ANEMIA.

The term "pernicious anemia" immediately suggests the well-known blood picture characterized by the diminution of the red blood cells with the retention of a relatively high hemoglobin content, the appearance of unripe erythrocytes, such as megaloblasts and megalocytes, normoblasts and normocytes, in the circulating blood, and finally a diminution in the number of leucocytes. Clinically, the term stands for a disease of unknown etiology, of varying duration, marked by repeated exacerbations and remissions and finally ending in a fatal outcome. Yet the creator of modern hematology, Paul Ehrlich, has clearly indicated the existence of another type of pernicious anemia, attention to which has been again called by the report of several recently observed cases. In contradistinction to the "hyperplastic" anemia described above in which the circulating blood shows evidences of active regeneration going on in the bone-marrow, this "aplastic" type of the disease is characterized by the absence of erythroblasts, that is, of unripe red cells in the circulating blood. Corresponding to the blood findings the bone-marrow shows singularly few evidence of erythrogenesis, being for the most part fatty in character, lacking almost totally in nucleated red cells and being very poor in the granular variety of leucocytes. Clinically, too, this variety of pernicious anemia differs from the usual type. Writing in Osler's Modern Medicine (Vol. IV.) Cabot thus summarises the principal data of the disease: Aplastic anemia is a disease of young persons. The number of cases occurring in women is much larger than in the ordinary type of pernicious anemia. The disease runs a rapid and progressive course. There are no remissions and the patient usually dies within a few months from the begin-

ning of the attack. Hemorrhages, subcutaneous, buccal, and elsewhere, are much more common than in the ordinary type of pernicious anemia.

The most interesting problem in connection with the existence of this separate variety of primary anemia lies in the possible light that it may throw upon the origin of pernicious anemia in general. That affection is no longer looked upon by the best authorities as a disease of the blood *per se;* rather, the phenomena observable in the study of the morphology of the blood are regarded merely as symptoms of the disease, evidences of the activity of some unknown poison which in producing hemolysis attacks in addition the internal organs such as the liver and the spleen, and the nervous system as well. The picture in the bone-marrow is simply the evidence of self-defense on the part of the organism, the attempt by overproducing to repair the damage caused by progressive hemolysis. That such an explanation is not far fetched is made evident by the brilliant researches of Schaumann who has shown that a disease that is clinically and pathologically very similar to pernicious anemia of the hyperplastic type is frequently produced by the presence in the body of a parasite, *Dibotriocephalus latus* or the fish tapeworm. Another observer, Bunting, has produced in animals bone-marrow lesions very similar to those observed in cases of pernicious anemia, by gradually poisoning them by injections of a hemolytic poison, ricin. Quite recently (Bulletin of the Johns Hopkins Hospital, February, 1910) L. Salling has reported a series of cases of purpura hæmorrhagica occurring among employees of a factory in which benzol was used. All the cases occurred in one room and all in common showed a marked degree of anemia, a purpuric eruption, and a blood picture closely akin to the one described above as typical of the aplastic type of pernicious anemia. What is more important, in the two cases that came to autopsy the bone-marrow was shown to have undergone the same degenerative changes as are found in aplastic anemia. Salling has produced similar changes in the marrow of rabbits by treating them with injections of benzol.

It seems evident, therefore, that the blood picture as well as its anatomical substratum, the changed bone-marrow, observed in cases of aplastic or hyperplastic anemia, may be produced by the action of substances which in the one case may be the products of animal metabolism or of the disintegration of animal protoplasm, in the other some chemical substance of unknown composition. The conclusion seems near that similar factors may be at work in the production of the cryptogenic pernicious anemia and the search for them should be the immediate aim of all interested in clearing up the problem of this remarkable affection.

A Simpler Typhoid Fever Test.

Though the discovery of the agglutination test for typhoid fever was unquestionably one of the greatest advances ever made in the diagnosis of this often obscure disease, it has the one disadvantage that if a positive Widal reaction is to be obtained the patient's blood must contain a fairly large proportion of immune substances, a condition not found in the early days of the disease, when the diagnostic need is greatest. For this reason many investigators have attempted to find some more delicate test for typhoid fever, or at least a test which will be of more value in the earlier days of the fever. In the *Münchener medizinische Wochenschrift* for January 25, 1910, Mandelbaum reports his researches in this direction. The basis of this work is the discovery by Pfaundler of the fact that colon bacilli, in a medium containing homologous immune serum, form a network composed of many long threads or chains of organisms, and the further finding by Kraus and Löw that typhoid bacilli, under similar conditions, first agglutinate and then some hours later grow into similar threads. Mandelbaum, thinking that possibly this thread-forming characteristic might make its appearance in the presence of serum containing a smaller number of immunity bodies than is required for the Widal test, has carried out some investigations which have resulted in his proposing the following test for typhoid fever: A citrate bouillon is made of the strength of two grams of sodium citrate to 100 c.c. of bouillon, and 5 to 8 c.c. of this is put in each test tube. Just before making the test one of these tubes is inoculated with an active but not too fresh culture of typhoid bacilli. A drop of the patient's blood is drawn into a sterile pipette, and following this about fifteen times its volume of the typhoid culture in the citrated bouillon. The pipette, after the lower end is sealed, is placed in the thermostat for four hours. The blood corpuscles sink to the bottom. With a second sterile pipette a drop of the supernatant fluid is placed upon a hanging-drop slide. If the blood is from a nontyphoid patient the bacteria are seen to be actively motile and separate, while if the reaction is positive they are in long, threadlike chains, and are not motile. Mandelbaum has used this test in a series of typhoid fever cases at various stages of the disease, and in a number of control cases, and he believes it to be as accurate as, and considerably more delicate than the Widal test, in a number of cases this reaction having been obtained some days earlier than the Widal.

Raynaud's Disease and Achylia Gastrica.

The symptom complex of symmetrical local asphyxia of the extremities, with its resultant gangrene of the fingers and toes, which is always associated with the name of Raynaud, is one of the pathological puzzles yet to be solved. Though malaria, syphilis, and other conditions are mentioned as the etiological factors in the disease, the actual knowledge goes little beyond the facts that it is associated with a marked vasoconstriction and is usually intermittent in character. An especially interesting case of this affection is reported by Friedman in the *American Journal of the Medical Sciences* for February, 1910. In this patient, besides the typical condition of local asphyxia of the fingers and toes, causing them first to appear white and dead and later of a bluish tint, there were a marked general anhidrosis and an intermittent achylia gastrica. The patient was under observation for some time, and numerous test meals were analyzed. In the periods between the attacks of local asphyxia the stomach contents showed nothing more striking than a mild grade of hypochlorhydria. At the time of the acute attacks, however, the test meal was removed practically unchanged by its sojourn in the stomach. It was very thick and dry, contained tenacious mucus,

and there was a total absence of free hydrochloric acid. This condition was observed on several occasions, always on cold days, associated with the increased cyanosis of the fingers, but giving no symptoms of indigestion. At the same time there was observed a marked contraction of the retinal arteries. The most plausible explanation of the association of these widely differing symptoms occurring in association would appear to be that the local asphyxia and cyanosis, the anhidrosis, and the achylia gastrica were all due to the same condition, vasomotor spasm in the parts affected, the underlying cause of which still remains to be demonstrated.

News of the Week.

Liability of a Hospital Interne.—A decision has recently been handed down by the United States Circuit Court of Appeals which is of considerable interest to the medical profession. Dr. A, a surgeon, operated on Mr. B and performed a nephrectomy in a Chicago hospital, Mr. B being a private patient. The wound was packed with gauze which was removed and changed by two internes, Drs. C & D and later by the family physician, Dr. E. Some months after returning to his home, the wound continuing to discharge, a second operation was performed by a local surgeon and a large piece of packing gauze was found in the wound. Mr. B sued Dr. A for malpractice and won a verdict of $4,000. This was appealed to the present court and the verdict reversed on the ground that the leaving of the gauze in the wound was due to negligence not upon the part of Dr. A but on the part of one of the two internes Dr. C or D, or the family physician, Dr. E, who had done most of the dressing, and that it would be mere guesswork to attempt to decide which of these men was legally responsible. In his opinion upon the question of responsibility of the surgeon for the mistakes of his hospital internes Justice Seaman said, as reported in the *Chicago Legal News*: "In Baker *vs.* Wentworth, 155 Mass. 338, this custom in respect of nurses is recognized, and the operating surgeon is held exempt from liability for negligence of the nurses * * *; and in Perionowski *vs.* Freeman, 4 Foster & F. 977, 980, Cockburn, C. J., remarked upon the practice (there proven) of surgeons to leave the care of their patients in various details to the hospital nurses, that such practice was 'indispensable,' and the operating surgeon was not liable for their negligence. So, these hospital attendants, known as internes (usually young physicians), are furnished at the general hospitals to attend to the ordinary work of dressing and treating the wound (left by an operation) on the way to recovery; and the mere undertaking of the surgeon to operate, under call or engagement therefor, cannot, as we believe, imply his further personal undertaking for the ordinary details of after-treatment, to make the doctrine of *respondeat superior* applicable, to charge him for fault or negligence on the part of such hospital attendants, neither known nor discoverable by the surgeon in the exercise of care and skill throughout his engagement."

A National Tuberculosis Sunday.—Announcement of a national tuberculosis Sunday to be held on April 24 in 215,000 churches of the United States has been made by the National Association for the Study and Prevention of Tuberculosis. It is planned that on April 24 tuberculosis sermons shall be preached in all the churches of the country. Literature will be distributed to members of the congregations, and in every way an effort will be made to teach that tuberculosis is a dangerous disease and that it can be prevented and cured. Clergyman who desire to obtain additional information in regard to tuberculosis will be able to secure literature from State and local antituberculosis associations and boards of health, as well as from the National Association.

The Harvey Society.—The seventh lecture of the Harvey Society will be delivered by Prof. Adolf Meyer of Johns Hopkins University, on Saturday, March 5, 1910, at the New York Academy of Medicine, at 8.30 P. M. The subject of the lecture will be "The Present Status of Aphasia and Its Relation to Psychopathology." The date of the lecture on diseases of metabolism to be given by Prof. Magnus-Levy of the University of Berlin has been changed from March 19 to April 2.

The Fourth International Sanitary Conference of the American Republics was held at San José, Costa Rica, December 25, 1909, to January 3, 1910. The following-named republics were represented at the conference by a total of 19 delegates: Chile, Colombia, Costa Rica, Cuba, Guatemala, Honduras, Mexico, Nicaragua, Panama, Salvador, United States of America, and Venezuela. In addition, the Bureau of American Republics also sent a representative. Dr. Juan J. Ulloa was president of the conference, with Dr. Luis Razette, Spanish secretary, and Dr. R. H. von Ezdorf, English secretary. The inaugural session was held at the National Theater December 25, 1909, at 3 P. M., and was attended by the President of the Republic of Costa Rica, Licenciado Don Cleto Gonzalez Viequez, his cabinet, and the Chief Justice of the Supreme Court. An address of welcome was made by the Minister of Foreign Affairs, Don Ricardo Fernandez Guardia, followed by that of the president of the convention, Dr. J. J. Ulloa. Short addresses were also made by a delegate on behalf of each republic represented. A large number of resolutions were adopted regarding sanitary conditions. The following were elected officers of the International Sanitary Bureau at Washington: *President*, Surgeon-General Walter Wyman, Public Health and Marine Hospital Service; *Secretary*, Juan J. Ulloa of Costa Rica; *Members*, Eduardo Liceaga of Mexico; Pablo Acosta Ortiz of Venezuela; Rhett Goode of United States; Juan Guiteras of Cuba; Manuel Camilo Vial of Chile. The following delegates to the Bureau from the United States were appointed: A. H. Glennan, J. W. Kerr and John W. Trask.

Antivivisection Bill.—On February 23, the usual annual hearing upon the antivivisection bill was held by the Assembly Judiciary Committee in Albany. The opposers of medical advance were represented by Mrs. Diana Belais of the New York Antivivisection Society, and Stephen Coleridge, the active head of the movement in England. The medical profession was represented in the argument by Dr. Simon Flexner of the Rockefeller Institute, Prof. Frederic S. Lee of the College of Physicians and Surgeons in New York, and Dr. James Ewing of the Cornell Medical School.

The Joseph Lawrence Free Public Hospital will soon be built in New London, Conn. The money for the building was provided by the will of the late Sebastian Duffy Lawrence in memory of his father. Two nieces of the late Mr. Lawrence, Mrs.

Pond and Mrs. Butler, have offered to furnish and equip the institution. At a recent meeting of the trustees an advisory committee was formed, consisting of the following gentlemen: Mr. F. S. Newcomb, Dr. John G. Stanton, and Dr. George S. Morgan, to procure data and estimates.

Donation to Toronto General Hospital.—The president of the Toronto General Hospital has announced that Mr. J. C. Eaton has donated $250,000 for the erection of the surgical wing of the main building of the proposed General Hospital on College street. It will be erected as a memorial to the late Timothy Eaton, father of the donor. The total number of beds to be provided for in the general surgical department is a hundred and forty-five. The trustees of the board found their resources represented by cash subscriptions of $600,000 from the University, private citizens $700,000, City of Toronto $200,000, making in all $1,500,000, with an approximate aggregate of $2,000,000 to be met.

University of Pennsylvania.—On the occasion of the celebration of University Day on Washington's birthday, Provost Harrison announced the following gifts: The Phipps' Institute for the Study, Prevention, and Treatment of Tuberculosis, with a benefaction of $500,000; the sum of $100,000 for the endowment of a chair whose occupant is to be known as the Benjamin Rush Professor of Physiologic Chemistry; a sum of money sufficient to complete the medical laboratories, in memory of the late James McManes, donated by his daughter; from Mrs. Caroline Emily Richmond, $50,000 for the endowment of ten beds in the University Hospital; from the Directors of the Pennsylvania Railroad, their exhibit worth more than $100,000, showing the development of railroad transportation from the earliest times until the present day. The announcement was made that the equipment of the University would be increased by the erection of a new zoological laboratory at a cost of $250,000. Also the Mask and Wig Club has created a fund already amounting to $5,000, the interest of which is for the time being to be used for general University purposes. A portrait of Dr. J. Wm. White was presented by Dr. Alfred Stengel on behalf of the donors.

Charitable Bequests.—By the will of the late Mrs. Ursula Kolbeck of Camden, N. J., the following charitable bequests are made: West Jersey Homeopathic Hospital, Home for the Indigent Aged and Incurable, Camden Day Nursery, West Jersey Orphanage for Destitute Colored Children, Camden Society for the Prevention of Cruelty to Animals, German Hospital of Philadelphia, German Society of Philadelphia, and the Nazarene Home for the Aged at Philadelphia, $300 each; the Camden Home for Friendless Children, the income from $1,200. By the will of the late Guilelma M. S. P. Jones of Philadelphia, the following bequests are made: Home for Aged and Infirm Colored Persons, the Home for Destitute Colored Children, the Pennsylvania Society to Protect Children from Cruelty, the William Foster Home of Tennessee, and the Ellwood Wilson Memorial Fund of the Philadelphia Lying-in-Charity, $500 each.

The Adirondack Cottage Sanatorium Laboratory has just received a gift of $25,000 from Mrs. E. H. Harriman, who donates this sum for a research and medical fund for the support of the sanatorium laboratory. The fund is to be known as the E. H. Harriman research and medical fund of the Adirondack Cottage Sanatorium. The interest is to be applied each year to the support of the sanatorium laboratory, which is distinct from the Saranac Lake laboratory at Dr. Trudeau's home in the village.

The Sacred Heart Hospital of Spokane, Washington, was opened on March 1, after three years spent in construction. The new hospital is said to be one of the best-equipped hospitals in the Northwest.

The University of North Carolina.—Following the action of the trustees of the University of North Carolina in voting to abolish the Raleigh department of the University School of Medicine, because of the lack of sufficient support from the Legislature to the University to warrant maintaining the Raleigh department of the Medical School on sufficiently creditable a scale to do justice to the State University, there comes the authoritative statement from parties close to the work in Raleigh that this will result in the establishment of a new medical college in Raleigh. The present faculty of the University department will meet within the next few days and take action, the conviction being that there is a great opportunity in Raleigh through the presence of Rex Hospital and Shaw University and St. Augustine Hospitals, and the other State hospitals, and the State and other laboratories, to which the students would have access.

An Examination for the Position of Medical Superintendent of Letchworth Village, the new State institution at Thielles, Rockland County, N. Y., for the epileptic and feeble-minded, will be held in April. Candidates must be citizens of the United States; at least thirty years of age; physicians in good and regular standing; with five years' practical experience in the care and treatment of the feeble-minded and epileptic. Salary, $4,500 per annum and maintenance for self and family. Full information and particulars regarding the nature of the examination may be obtained by addressing the State Civil Service Commission, Albany, N. Y.

The Alumni Association of Mount Sinai Hospital in New York gave a dinner on Saturday evening, February 26, to celebrate Dr. A. Jacobi's half-century of service. A gold medallion portraying the doctor, executed by Mowbray Clark, sculptor, was the gift of the Association to Dr. Jacobi. The speakers of the evening were Dr. Martin W. Ware, president of the Alumni Association; Prof. William H. Welch of Johns Hopkins University; Dr. John A. Wyeth, president of the New York Academy of Medicine, and Drs. Charles H. May and A. G. Gerster, attending surgeons to the hospital, and Philip Goodhart of the Board of Directors.

Obituary Notes.—Dr. John Gray of Bridgeport, Conn., died on February 17, 1910, aged eighty-nine years. He was a graduate of the Yale Medical School in 1843, and had practised medicine in Mystic, Conn., for over sixty years.

Dr. Charles Paine Thayer of Boston died at Atlantic City, recently, aged 67 years. He was a graduate of the University of Vermont College of Medicine in 1865. For many years Dr. Thayer was dean and professor of anatomy in Tufts Medical College. He was a member of the Suffolk County Medical Society and the Massachusetts Medical Society.

Dr. George Lucius Beardsley of Derby, Conn., died of Bright's disease at the New Haven Hospital on February 26. He was born in Milford, Conn., May 12, 1848, being a son of Dr. Lucius N. Beardsley. He received his preliminary education at the Milford high school and at the Hopkins grammar school, and was graduated from Yale with the class of 1870. He attended the Bellevue Hospital Medical College, New York, there receiving his medical degree, and subsequently was appointed surgeon in charge of the outdoor department for the surgical relief of the poor, remaining there until the fall of 1874. He opened an office in New Haven, but remained in that city only a few months, going to Derby in 1875. He was for five years assistant surgeon of the Second Regiment, C. N. G. About 1885 he was appointed medical examiner for Derby, and held that office at the time of his death. He was one of the surgeons on the staff of the Griffin Hospital, and was to have served his first term beginning with April. Dr. Beardsley is survived by his wife and by two children, Alling Prudden Beardsley and Miss Elizabeth Coley Beardsley. He also leaves a brother, Dr. William E. Beardsley, of Brooklyn, New York.

Dr. Augustus Henry Dieck of New York died at his home February 16, 1910, aged 91 years. He was a graduate of the University of Göttingen, in 1842, and had practised medicine in New York City from 1845 until ten years ago, when he retired from active work.

Dr. James Mulhern of Grand Rapids, Mich., died at his home on February 9, 1910, at the age of 66 years. He was a graduate of the Detroit Medical College in 1870, and was a member of the Kent County Medical Society, and the Michigan State Medical Society.

Dr. James E. Tuell of Augusta, Me., died on February 11, 1910, aged 55 years. He was a graduate of the Jefferson Medical College in 1884, and was a member of the Kennebec County Medical Society, the Maine Medical Association, and the American Medical Association.

Dr. Monroe Budd Long of Plainfield, N. J., died February 20, 1910, aged 60 years. He was a graduate of the College of Physicians and Surgeons in New York in 1874. Dr. Long was surgeon to the Muhlenberg Hospital and a member of the Plainfield Medical Society, the Union County Medical Society, the Medical Society of New Jersey, and the American Medical Association.

Dr. George Howard Palmer of Brooklyn died at his home on February 18, 1910, aged 47 years. He was a graduate of the New York University Medical College in 1884.

Dr. L. Barstow Irish of Brooklyn died at his home on February 17, 1910, aged 75 years. He was a graduate of the Bellevue Hospital Medical College in 1860.

Dr. William Henry Walling of Atlantic City died on February 17, 1910, aged 73 years. He was a graduate of the Medico-Chirurgical College of Philadelphia and had been on the staffs of the Medico-Chirurgical Hospital and the Wills Eye Hospital. Dr. Walling was a surgeon in the Civil War and edited the *Medical Times and Register*.

Dr. Frank Howard of San Antonio, Tex., died at his home, February 7, 1910, aged 38 years. He was a graduate of the Barnes Medical College in 1898.

Dr. Wm. B. Stanton of Philadelphia died on February 13 at the age of 38 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1898 and he served as resident physician in the Hospital of the University. He was one of the visiting physicians to St. Agnes Hospital and to the Sanatorium for Tuberculosis at White Haven, Pa. He had devised a practicable sphygmomanometer.

Dr. Charles F. Spangler of Kane, Pa., died of pulmonary tuberculosis at York, Pa., on February 13, at the age of 51 years. He was graduated from Jefferson Medical College in the class of 1881.

Dr. William Gregory Macdonald of Boston died on February 9, 1910, at the age of 51 years. He was a graduate of Boston College in 1880 and of the Harvard Medical School in 1884. Besides serving as house surgeon at Carney Hospital and admitting surgeon to the Massachusetts General Hospital, he was physician to the county jail, and the smallpox hospital, and dermatologist to the Carney, St. Elizabeth, and Mt. Sinai Hospitals. For many years Dr. Macdonald was associated with the Board of Health as medical inspector and city physician. At the time of his death he was medical examiner of Suffolk County. He was a member of the Suffolk County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. Edgar Ivory Hanscom of Providence, R. I., died February 19, 1910, aged thirty-eight years. He was a graduate of Bates College in 1896 and of the Maine Medical School in 1903. At the time of his death Dr. Hanscom was assistant physician to the State Hospital for the Insane in Providence.

Dr. William King of Brunswick, Me., died at Augusta February 15, 1910, aged fifty-two years. He was a graduate of Bowdoin College in 1881, and of the Medical School of Maine in 1887.

Dr. Daniel H. Law of Dixon, Ill., died in Brownsville, Tex., on February 15, 1910, aged seventy-eight years. He was a graduate of the Keokuk Medical College in 1861, and a battalion surgeon during the Civil War. He was a member of the Lee County Medical Society, the Illinois State Medical Society, and the American Medical Association.

Dr. Augustus Richter of Williamsport, Pa., died on February 20, at the age of eighty years. He was graduated from the Pennsylvania Medical College in the Class of 1851. He was the oldest member of the Lycoming County Medical Society.

Correspondence.

A MODIFIED ESMARCH INHALER.

To the Editor of the Medical Record:

Sir:—The need of an inhaler that will fit any face accurately in using the drop method of anesthesia has long been felt. Whether we use ether, chloroform, or ethyl chloride on an open mask we want that mask to fit firmly over the nose and mouth. I think I have solved this problem. I have had a mask made along the lines of the Esmarch inhaler, but of a flexible material instead of steel. At the suggestion of Mr. Frech, of the firm of J. T. Dougherty, I used copper wire, nickel plated. I have left off the gauze and its holder and use flannel, or better still, thick stockinette, cut the proper size and turned in at the edge with a draw string of tape or thick silk suture material. The cover is put on the wire frame and the draw string tightened, thereby keeping the cover in place. Just before starting the anesthesia the mask is bent to suit. Because it fits, it is easily held on the face with one finger.

Alfred M. Hellman, M.D.,
Anesthetist to the German and Har Moriah Hospitals.
2 West Eighty-sixth Street.

PELLAGRA—TRYPANOSOMATA—CANCER IN RATS AND MICE—COLOR-BLINDNESS—ANESTHESIA—UNIVERSITY ELECTION.

LONDON, February 11, 1910.

PELLAGRA has been a prevailing topic of the week among doctors, and many of their patients have been asking what it is. This interest has been excited by the formation of a strong committee, on which the London and Liverpool Schools of Tropical Medicine are both represented, with a view of a new investigation of the disease. It is true that it does not prevail in this country, but it does in some parts of the empire. The committee has appealed for funds and met with an encouraging response. The *Times* of Friday last had an instructive article on the subject and the other daily papers have followed suit. It is intended to send Dr. Sambon to the pellagrous areas to carry out a complete research. He is, as you know, dissatisfied with the prevailing views as to the origin of the disease. Indeed, I may say he utterly repudiates the so-called Monje theory and has propounded another hypothesis, which has met with a favorable reception from a number of continental authorities, and also, I think, from able observers on your side since some of the States have been invaded. His hypothesis is that pellagra is a protozoal disease conveyed by one of the blood-sucking insects, and he thinks that a sandfly will probably be found to be the carrier. This would bring it into relation with other parasitic infections. His first work will be directed to determine whether this theory can be established. If it cannot he will proceed to investigate all circumstances connected with the disease by the aid of all the facts and specimens he will have accumulated and carry on all kinds of research which may help to determine its true etiology and pathology.

The Royal Society's meeting on Friday last (3d inst.) was of medical and biological interest. Professor Minchin described some experiments conducted by himself and Mr. J. D. Thomson on the transmission of *Trypanosoma lewisi* by the *Cerotodus fasciatus* (rat-flea). They came to the conclusion that the flea did not act merely as an instrument or as a carrier of infection, but that it was the seat of a cycle of development in the parasite, as was the mosquito in the case of the malaria parasite. This they expressed briefly in the statement that transmission from an infected rat to a noninfected one is by the cyclical, not by the direct, method. They further determined that in the flea the incubation period was at least six days, but that it might be longer.

Dr. E. F. Bashford brought forward a paper by Dr. Medigreceanu of Bukarest on the relative sizes of the organs of rats and mice bearing malignant growths, the most important result of which was that the liver is enlarged in animals bearing carcinomata and sarcomata, whether these growths are transplanted or arise naturally. Dr. Bashford also presented a paper by himself and Dr. B. R. G. Russell on the homogeneity of the resistance to the implantation of malignant growths. It was stated by Dr. Bashford that the prevailing conceptions of what constituted immunity to cancer were simplified by experiments showing that the active immunity which followed in rats after a preliminary inoculation of mouse cancer was not an immunity against cancer but against the protein of a foreign species. Consequently hypotheses of cancer immunity based on the study of the behavior of tumors in strange species had at most only an indirect bearing on the immunity to cancer of the same species.

Another paper by Dr. M. Haaland (also presented by Dr. Bashford). In this the reactions to the implantation of cancer after the inoculation of living and of mechanically disintegrated cells were contrasted.

The subject of color blindness is sure to come up for fresh discussion whenever an accident occurs which might have been due to it. Accordingly it has again been before the public, and the profession is asked for explanations.

Dr. Edridge-Green, who has for years studied the condition in all its aspects, read a paper on it at the Society of Arts on Wednesday, in which he maintained, as he has often done before, that the wool test has proved a failure, although it is still used by the Board of Trade. He hoped a committee would be appointed soon to examine the facts, for he had proved that many dangerously color-blind men had passed that test and his experience was confirmed by others. Of those rejected by the wool test and who appealed over 53 per cent. were found to be normal-sighted. The material was not a good one, for it was difficult to obtain correctly colored wools. A further difficulty was found in obtaining duplicates of these wools. If two colors looked alike they had not necessarily the same composition; if the dyes used were different the colors would probably differ in composition. Further, when a good set of wools had been secured, the colors were liable to fade, some more rapidly than others. This would prevent the results of examinations made with that set from being uniform. Then the wools, or some of them, would very soon become soiled. The greens which it was necessary to pick out would get more soiled than the others and so afford a mark of distinction to the color-blind, who, not being confused by the striking differences of color, noticed minutiæ of this kind. In testing a number of persons the color-blind ones would try to find some distinguishing mark in wools selected by others. Color-blind people might distinguish between brown and green by the touch, but not by sight. The relative luminosity of the colors of wools was also considerable and formed a distinguishing point to the color-blind. A pure green was one of the worst possible colors to choose for a first test. If the blue-green were removed, color-blind persons might easily pass through the whole list and not be detected. Dr. Eldridge-Green held that the test was theoretical rather than practical, the main object of testing being lost sight of. Thus it had to be proved that a man who put a confusion-color with a green wool could not tell a red from a green light, and when he had done so it was still to be decided whether he had been judging more by shade than color. In fact, it was obvious the test was by no means efficient. They could not reject by it those who would be dangerous as sailors or engine drivers—and only those persons. Moreover, it was possible to instruct a red-green color-blind person so as to enable him to pass through the test with ease.

Yesterday the poll of the Universities of Edinburgh and St. Andrews was declared. Sir Robert Finlay was elected by a majority of 2,512 votes over Sir A. R. Simpson. The numbers were 5,205 against 2,693.

Yesterday the Council of the Royal College of Surgeons adopted a report brought up by their committee on the administration of anesthetics, which expressed concurrence with the conclusions of the General Medical Council, except so far as any limitation of dental practitioners to cases in their own specialty. It was felt that very often anesthesia is needed when a medical man, in addition to the operator, cannot be obtained, and in such cases it would be well for a qualified dentist to administer the anesthetic.

(From Our Regular Correspondent.)

SPOROTRICHOSIS BEURMANNII—ATONIC GASTROPTOSIS—SUTURE OF THE HEART—CARDIAC PAIN—THERAPEUTIC ACTION OF A BULLET WOUND—PROMINENT EARS.

VIENNA, January 31, 1910.

AT the Society of Physicians Otto Krenn demonstrated a case of *Sporotrichosis Beurmannii*. The patient suffered from a disease which was first described in 1903. Up to date no case had been published from Austria. The cause of the disease is the *Sporatrichon Beurmannii* This is a thin sigmented spore-bearing thread. The skin disease caused by it appears in two forms, the syphiloid form, papules which pustulate, or the tubercular form, which resembles lupus. As a rule the disease has an afebrile course, but occasionally acute cases occur which may show the appearances of septicopyemia. Potassium iodide has a favorable action when the disease is localized to the periosteum or the bones.

After this presentation Ricard Volk demonstrated a preparation of experimental sporotrichosis. The infection was produced by an original culture obtained from Ravant. Various animals are susceptible, especially dogs, cats, and rats. Different morbid pictures are produced, according to the mode of infection and the character of the animal, some of them closely resembling the lesion seen in human skin. For example, if one inoculates an animal intraperitoneally the symptoms appear at the end of ten to fourteen days. The first signs of disease appear in the testicles in the form

of small nodules, which shine white through the tunica albuginea, closely resembling tubercles. At the same time the organ increases rapidly in size. The further course shows nodule formation in the omentum, peritoneum, lungs, and liver, so that the various organs may show disease pictures. Finally, the animals die, with the appearance of severe cachexia. The autopsy shows, besides the nodules, degenerations of the parenchymatous organs and a marked watery condition of the blood, and furthermore from the adhesion of the testicles to the skin there may be an ulceration resembling a gumma. On the position of the organism biologically the researches are not conclusive. It is a fact that the organisms in a section of human sporotrichosis appears to be very difficult or impossible to stain, whereas those found in experimental infections stain easily.

At the same society Professor van Noorden spoke on the subject of ptosis and atonia of the stomach. In the treatment of atonic gastroptosis we use above all other methods the abdominal binder and the forced feeding cure, both in the effort to raise the sunken pylorus. Even well-adjusted abdominal binders and properly applied adhesive plaster are of no value if the abdominal wall has its normal tone. However, under these circumstances much may be accomplished by a feeding cure lasting from four to six weeks. The forced feeding in cases of stomach disease is not especially easy, particularly in these cases of gastric atony. Besides the elevation of the lower border of the stomach and the entire pyloric portion, a marked shortening of the entire organ occurs and in those cases where the lower curvature bulges downwards like a pouch this bulging disappears. The filling of the peritoneal cavity with fat plays an important part in the results, but the chief factor in the cure is the increased tone of the stomach wall brought about by the improved general nutrition. Rest in bed is unnecessary during this form of treatment.

Professor Schnitzler has had a case of suture of the heart. The cardiac wound was the result of a knife stab over the precordium. The operation, carried on under anesthesia, in the course of which the fourth and fifth costal cartilages were removed, showed a wound in the pleura, a wound in the pericardium, and a cut 1.5 cm. long in the anterior wall of the right ventricle, penetrating the entire thickness of the wall. The catgut suture which was applied first tore out and very profuse hemorrhage occurred from the right ventricle, provisionally controlled with the finger. With great difficulty, owing to the turbulent action of the heart a deep wide suture was taken with silk, and by means of this the heart was drawn forward. After this it was easy to apply three superficial silk sutures, which accurately closed the opening into the ventricle. The pericardium was closed and the left pleura drained. The further course of the case included a left-sided hemopneumothorax, complicated a few days after the operation by a right-sided croupous pneumonia, with diplococci in the sputum, and herpes labialis. As a result of these, repeated punctures, counter drainage, and finally twice resection of the ribs were required, complications and sequelæ of operation not rare after cardiac suture. At present there is still a small pleural fistula, but except for this the patient may be considered as completely cured. The statistics of cardiac suture show from 30 to 40 per cent. of cures. The majority of the causes of death following cardiac suture are infectious complications on the part of the pericardium and the pleura. In the recovering cases these complications often make the convalescence slow and difficult.

In the German Medical Society at Prague, Selig of Franzensbad spoke on the subject of cardiac pain. The sensations in the cardiac region of which nearly all cardiac cases complain have various causes and characteristics. As a cause of the most common cardiac sensation, palpitation, must be considered the strong contraction of the heart in answer to the great demand of the active organs. The chief immediate cause is a psychic alteration. With a nervous foundation the smallest psychic impulse suffices to produce it. Most sufferers from heart disease have cardiac anxiety, a feeling of anguish which often stands in direct relation to the heart disease, as coronary sclerosis or myocarditis. This cardiac anguish reaches its maximum in angina pectoris a definite symptom complex. Arteriosclerosis is not always the cause of these sensations; abuse of tobacco is very often responsible and also vasomotor influences. Alterations in rhythm on occasion call forth the hypersensation. The differentiation between nervous and myocarditic arrhythmias is difficult and renders correct diagnosis and prognosis hard to make. There are cases of the most extreme arrhythmia which we are obliged to consider as nervous because the heart shows no insufficiency even with violent exercise. The occurrence of an attack often calls forth the most unpleasant symptoms in the region of the heart, stabbing pain in the heart, oppression and dizziness due to incomplete cardiac contraction. Intercostal neuralgia and vasomotor conditions frequently cause pain in the region of the heart. Hot fomentations to the pericardium, or a hot water bottle, serve well in the treatment of cardiac pain in arteriosclerosis. Women with heavy, fat, hanging breasts complain of continuous pain in the heart, which completely disappears on supporting the left breast. Constipation and flatulence press upon the heart by raising the diaphragm; certain foods or hunger cause palpitation in that they influence the gastric branch of the vagus nerve either by stimulation or inhibition. Incorrect proportions between the size of the heart and the thorax must be put in the list of causes of oppression. One of the most important causes of cardiac pain is insufficient suspension of the organ, the so-called wandering heart, which allows of the most various dislocations.

In the Society of Physicians Prof. Schnitzler showed a case in which a revolver shot acted to cure a disease. The bullet entered the abdomen. The laparotomy showed two perforations of the jejunum and hyperemia of the descending colon. The intestines were sutured and the abdomen closed. Schnitzler reported the case not on account of the indications for operation and the uneventful postoperative course, as he considered it as a matter of course that one should do a laparotomy in a fresh abdominal bullet wound, under these conditions, and it as a rule happens that such cases operated upon in the first hours recover; but because the laparotomy served to demonstrate a most interesting complication. The entire length of the small intestine examined was covered with tubercles; the walls were infiltrated, and deep ulcerations were seen. In the peritonium was a serous exudate, naturally somewhat blood tinged. The patient had shown no symptoms whatever of this extensive intestinal tuberculosis. Schnitzler naturally inquired into this carefully after she recovered. For years she had had no irregularities of the bowels, no diarrhea, no increased frequency of motions; she was not emaciated, had no fever, and no pain. In several admissions to the hospital she had shown no symptoms of disease of the intestines or peritoneum. Ten years previous the patient had had tuberculosis of the tarsus, which had healed completely after operation. She gave a very active ophthalmoreaction. It is well known that intestinal tuberculosis may run its course unrecognized and be discovered first at the autopsy table. This, however, usually happens in very ill people, in whom the tuberculosis of the lungs or other organs masks the picture, whereas in this case the advanced tuberculosis was found in a woman apparently perfectly well and only discovered as a result of the laparotomy performed for the bullet wound. It is not certain that the laparotomy had anything to do with the recovery, but at least the tuberculosis in no way interfered with the healing of the intestinal wounds.

Dr. Erich Rutlin has devised a new method of correcting prominent ears. The method is as follows: First one orients himself by pressing the ear back against the head and finds how much of the surface of the pinna and the mastoid process come in contact when the ear is in the corrected position. Then, at a point 1 cm. posterior to this marked line, a curved incision is made the length of the pinna. (For example, this cut is 4 cm. from the root of the pinna.) Then on the posterior surface of the pinna, parallel to the first cut, but half as far from the root of the pinna (that is, 2 cm.), is made a second cut. The skin lying between these two cuts is excised and the skin of the posterior surface of the pinna for a distance of 1 cm. is freed. Then the two cut edges of skin, after the necessary trimming has been done, are approximated and sutured. By this the freshly denuded surface of the pinna is brought in contact with the similar surface of the mastoid. The pinna is held in this position by a compression bandage for fourteen days, until the surfaces have united. The advantage of this method is the strong fleshy union, and further that the cartilage and pericondrium are preserved intact and that as one uses the skin for the plastic material he has the whole integument covering pinna and mastoid with which to work.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

EHRLICH'S THEORY OF CHEMOTHERAPY OF INFECTIOUS DISEASES.

BERLIN, January 30, 1910.

THE Central Committee for Medical Progress in Prussia arranges each winter a series of lectures in which the accepted authorities in Germany discuss the themes in which they are credited with especial knowledge. The course this year deals with "Infections—Their Recognition and Treatment." Of especial interest was the address by Paul Ehrlich of Frankfort, who spoke on the chemotherapy of the infectious diseases, the substance of which may well be given in brief.

Chemotherapy and immunotherapy have a general relation to each other in so far as by both, on the introduction of a material into the body, antibodies are produced. The immunotherapy or serum therapy, however, will always have the superiority over all other therapeutic measures, in that it is absolutely specific, not in the least injuring the body, but acting upon the bacteria only. In a number of diseases, however, to which belong especially those produced by protozoa, as malaria and sleeping sickness, and by pathogenic spirilla, immunotherapy seems powerless to produce an antibody with a curative power. In these cases recourse must be taken to chemotherapy. The best results of this are obtained with quinine in malaria, iodides and mercury in syphilis, and atoxyl in trypanosomiasis.

The foundation of the sphere of chemotherapy is the changing of the chemical law, *Corpora non agunt nisi liquida,* into the chemotherapeutic law, *Corpora non agunt nisi fixata*; that is, unless the drug is taken up by the parasite or is, as Ehrlich calls it, "parasitotropic." As all these drugs are also taken up by the organs of the body, or are organotropic, the organotropia and parasitotropia of any drug must exist in the proper proportion.

For the occurrence of parasitotropia the best example is given by a study of trypanosomiasis, especially of the acid-fast strains of the organism. Three groups of chemicals—arsenicals, certain azo pigments, and certain basic triphenylmethan pigments—show curative properties for animals infected with trypanosomes. In the trypanosomes a definite portion of its protoplasm must be considered to be a chemoceptor, as this portion is able to form a combination with a definite chemical: for example, trivalent arsenic.

In order to test a drug, by putting it in a test tube and allowing it to work on the bacteria the motility and agglutination of the latter may be observed, or else it may be injected into animals. When this is done there are three possibilities. 1. *In vitro,* and in the animals the drug has no action; that is, the trypanosomes have no specific chemoceptors. 2. The action *in vitro* is marked, while in the animal body it is absent. This occurs when the drug combines *in toto* with the organs and not at all with the parasites. 3. The drug is inactive *in vitro,* but very active in the animal. This may be explained in two ways. First, it may happen that in the body, from the inactive chemical substance, by the transforming power of the body an active chemical substance is produced. Second, it is possible that while both in the test tube and in the body the activity of the parasite is uninfluenced, its reproductive power on the other hand is inhibited. When dealing with short-lived parasites such an action naturally cures the disease. Furthermore, cases often occur in which the action in the test tube is much weaker than in the animal. This can be explained on the theory that a part of the parasites may be killed by the drug, just as in the test tube, the dead parasites, however, then producing antibodies in the animal which act on the living parasites.

After the discovery of acid-fast strains of trypanosomes, Ehrlich sought for a drug which would act upon these. This was found in arsenophenylglycin. After much research it was established that the activity of this could be explained only on the theory that there exists in the trypanosomes a peculiar side chain, which has a special affinity for the acetic acid radicle of the arsenophenylglycin and must, therefore, be called an "aceticoceptor." It is possible, furthermore, that the drug may combine not only with one but with more groups of the parasite protoplasm. In this case there can be proved experimentally a primary combining group, called a primary haptophor, and a secondary one, a secondary haptophor. It has been shown further that in the spirilla diseases iodine plays a great rôle. In the spirilla there is present a group which, in a preparation of arsenic iodide, first combines with the iodine-iodoceptor as primary haptophor—and only afterwards with the other portion of the drug. It may be broadly stated that for each kind of parasite there exists a characteristic side grouping of chemotherapeutic power, with the help of which a definitely highly therapeutic radicle, for example, iodine or mercury, may be found with which it is possible to attack the especial parasite.

Following out this line, a coworker of Ehrlich has succeeded in obtaining most excellent curative results with a phenyl arsenous acid preparation in various spirilla diseases, as chicken spirilosis, relapsing, fever in mice, and rabbit syphilis. By one injection it was possible completely to cure a very large chancre on the testicle of a rabbit.

In the application of these animal experiments to man there are a number of difficulties to be fought: (1) It is impossible in man to determine the maximum dose of the drug. The limits of safety must be discovered by very careful investigation from below upward. (2) The frequent appearance in man of hypersensitiveness to the drug interferes greatly with the search. The estimation of hypersensibility is the most important factor in the application of a new drug. Two methods come into consideration in the case of men—the step-ladder method of treatment, beginning with small doses regularly repeated, and the method of using massive doses for one or two days for the rapid and complete slaughter of the parasites. The latter method, which destroys the cause of infection with a single stroke, may be compared to the surgeon's knife—the more dangerous but at the same time the more effectual plan. Just as surgery has reached its present high position only by advancing with a certain boldness, so, too, a certain risk must be accepted in the paths of therapeutics in using single large doses when the superiority of the method over the other has once been established. In this case the motto should not be *primum non noceas,* but *primum ut proficeas.*

Progress of Medical Science.

Boston Medical and Surgical Journal, February 17, 1910.

The Influence of Race on the Infant Mortality of Boston in 1909.—Richard C. Cabot and Edith K. Richie have endeavored to answer the following questions: Among the races most numerous in Boston, is any one predominately affected (a) by all the causes of infant mortality, prenatal, and post-natal; (b) by certain special causes. Do the hygienic, moral, or economic traditions which govern any one of the races (Irish, Jew, Italian, or "American") result in making one disease especially afflict one race? They conclude as follows: 1. The Jewish race in Boston far exceeds any other (a) in the number of stillborn babies and (b) of digestive troubles proving fatal during the first two years of life. 2. The Italians suffered during 1909 far out of proportion as compared with the other races in the infant mortality from infectious disease outside the gastrointestinal tract. The great bulk of these deaths was due to pneumonia. On the other hand, the Italian race is more fortunate than any other race in Boston in that it loses a far smaller number of children from congenital weaknesses, prematurity, and birth accidents. 3. The Irish have the best record as regards still births, and lose a remarkably small number of babies from infectious diseases. They fare better than the Jews or Italians as regards practically every one of the causes of infant mortality, though in all these respects, except as regards prematurity, their record is somewhat worse than the "Americans." 4. As might be expected from their longer settlement in this country, the so-called "American" race loses fewer children per thousand births than any other race. This advantage holds good as regards every one of the causes of post-natal mortality with the exception of those classed under the term "prematurity." In deaths from this cause the "American" race has the worst record of all, and in the number of stillbirths the "Americans" are far more afflicted than the Irish and almost equal to Italians, though the Jews fare worse still.

An Obscure Affection of the Hip-Joint.—Arthur T. Legg relates the history of five cases, in reviewing which the following facts in a general way are observed: The age of the children was from five to eight years. In each case there was history of an injury and a limp. Thicken-

ing around the neck of the femur was observed. There was absence of pain and of constitutional symptoms. There was little or no spasm and absence of shortening. In one case there was indefinite pain and a low grade of infection in the neck of the femur. All of the cases sought advice solely on account of the limp. In two of the cases the condition of flattening of the head of the femur existed on both sides and in both there was entire absence of symptoms in one of the hips. Was this condition the result of congenital deformity or faulty development? Was it the result of constitutional disease? Was it the result of direct injury? Was it indirectly due to the injury? The histories ruled out the possibility of a deformed and poorly developed head of the femur. A possible explanation of the condition was that the injury might indirectly cause this condition by causing injury or displacement at the epiphyseal line, whereby the nutrition of the head, coming mostly through the neck, was impaired, and by the poorly nourished epiphysis bearing on the acetabulum it becomes flattened. Dr. Legg makes no claim to a definite conclusion.

A Simple and Clean Instrument for Vaccination.—This instrument, invented by Francis H. Williams, consists of a piece of stiff platinum wire, 1 mm. in diameter and 5 cm. long, fused into a piece of glass tubing which serves as handle. The other end of the wire is flattened by means of a hammer to a width of rather more than 2 mm., and has been well rounded with a file and its edge roughened by making shallow cuts in it with a knife blade. This roughening is important. The platinum wire is sterilized by heating to a red heat; it cools in a moment.

New York Medical Journal, February 19, 1910.

Thymus Gland Treatment of Certain Diseases.—Frederick Gwyer gives a report of some experimental work in goiter, arteriosclerosis, rheumatoid arthritis, cystic tumor of the breast, pulmonary tuberculosis, and cancer. He did not know of any previous use of the thymus gland in the treatment of any disease except gout, goiter, and metabolic osteoarthritis. He selected the thymus gland as theoretically possessing possibilities in the treatment of cancer, and his work during the past three or four years has been confined to the use of this gland. With but one or two exceptions, no case of cancer has been treated that could even be benefited by other means. The histories of a number of patients were given as illustrative of the action of thymus; these patients received thymus and no other medication, and in most of them the improvement was so prompt and continuous that there could be no question but that it was due to thymus. Either the dried powdered thymus was used in doses varying from 129 grains, three or four times a day, to one of the special preparations. The improvements in three cases of pulmonary tuberculosis was significant and he believed that a further trial of thymus in tuberculosis was not only justifiable, but was demanded. Most of his cancer cases are remaining stationary or showing improvement and, taking cancer for test cases, he was encouraged to believe that he was approaching that primary substance which would enable him to decide definitely the value of thymus treatment of disease. In conclusion he said that at the end of three years' work, he was more than ever fixed in his belief that in thymus will eventually be found a valuable treatment for cancer, for that class of diseases due to improper metabolism, and possibly for tuberculosis.

Piper Methysticum, or Kava, and Its Effects in Gonorrhea.—This contribution to physiological therapeutics is given by Paul Bartholow. The action of cavaine is confined to an influence over the sense of pain and to an influence perhaps not so great over the development of microorganisms. The internal effects of cavaine he divides into three groups. (1) On the alimentary tract. One or two-drop doses cause warmth and a sense of appetite, and gives to the breath a penetrating odor of pepper. It stimulates digestion and its medicinal use seldom deranges the stomach. (2) On the kidneys and urethra. Cavaine has come to be restricted almost entirely to the treatment of acute gonorrhea and cystitis. It is a gentle diuretic. It acts directly upon the ends of the nerves in the mucous membrane, causing a soothing effect. Cavaine certainly is too unchangeable to be much modified by the urine, but whatever modification is caused by cavaine in the urine brings one to an explanation of its value in gonorrhea. (3) On modes of decomposition. Upon the presence of cavaine in the urine depends the healing qualities of the urine, the absence of decomposition, thus affording nothing that could favor the growth of gonococci; its effect in relieving pain facilitates the use of injections. Cavaine retards the formation of ammonia. According to Pohl's experience, certain plants, remarkable for their odor and bitter properties, possess the power of increasing the number of leucocytes in the circulating blood; they provide alexins. Cavaine, as one of the *Piperacea*, falls under this denomination and so confers some degree of immunity. The dose of cavaine is 0.02 four or five times a day, but two doses may be taken with profit at the noonday and evening meals. In his cases its most predominant effects were sedative and antiseptic.

Journal of the American Medical Association, Feb. 19, 1910.

Luetic Lymphoma.—D. W. Montgomery and G. D. Culver describe a case of swelling of the neck, resembling a lymphosarcoma, in the classical position for such a tumor. A study of the case almost confirmed this diagnosis, as there was a negative history of lues given by the patient, which was not modified by any admissions in view of the serious nature of the operation required for lymphosarcoma. The bad prognosis of such procedures, however, induced the authors to try a vigorous antisyphilitic treatment by injections and by the mouth, which proved successful. Later information gave a suspicious history confirming the diagnosis. The diagnosis of these cases is discussed at length, and the rarity of luetic lymphomas noted. The authors suggest for such cases that the proper attitude should be to consider the possibility of syphilis and to use a very vigorous course of antisyphilitic treatment before assuming that there must necessarily be a malignant lymphosarcoma to treat, necessitating an almost hopeless surgical operation.

Early Abdominal Surgery.—H. O. Marcy contributes a paper full of interesting reminiscences of the earlier gynecologists of this country, as well as some of the noted European introducers of antiseptic surgery. The introduction of antiseptic surgery into America and the part he personally took are briefly mentioned. The buried animal suture, which in other papers he has shown to be one of the advantages due to an early generation of American surgeons, owes its practical introduction and use to the teachings of Lister. Marcy attributes the large part taken by America in contributing the important factors in the advance of surgery to the open-mindedness of her students who, without national prejudice, sought profit from all sources.

General Therapeutics and Surgery in Dentistry.—A. Dray holds that the dentist does not fulfill all his duties in the care of the teeth by restricting himself so much, as he ordinarily does, to the mechanical side of his profession. As a mechanic, the average dentist excels, but as a scientific student and follower of surgery and general medicine applicable to dentistry he fails. Much of the mechanical labor performed could be obviated by the proper use of scientific research work in the fields of preventive and curative medicine. He condemns the commercialism of the dental schools, which are but schools of mechanics under the present system. Unless the dentist is satisfied to be looked on as a mechanic, he must make a radical change in his preparation for his life's work. A thorough general medical and surgical training along special lines pertaining to general medical and surgical dentistry along with scientific research work in the same field are the crying needs of to-day.

Suppurative Perigastritis.—G. A. Friedman reports a case of suppurative perigastritis caused by gastric ulcer perforating the stomach and producing localized peritonitis. The symptoms were somewhat aberrant. The tumor did not occur in the left epigastrium but in the right. Vomiting was never a pronounced symptom, and the nutrition of the patient had not greatly suffered. The importance of recognizing latent gastric ulcer in these cases is especially emphasized. Recovery followed the removal of a mass the size of a small orange, containing areas of necrosis and small abscess cavities, which was adherent to the liver, abdominal parietes, and greater curvature of the stomach.

Calcium in Tuberculosis.—L. A. Levison has experimented with giving lactate of calcium, 0.3 gram, every 4 hours to 30 patients suffering with tuberculosis with more or less marked continuous elevation of temperature. No attempt was made to select patients in special stages of the disease, and no change made in the other methods of treatment employed. Only four were suffering from tuberculosis other than pulmonary. The period of the administration was short and the conclusion which may be reasonably drawn is that pyretic tuberculous patients in various stages show no response as far as temperature is concerned to the administration by the mouth of calcium salts.

Epidemic Poliomyelitis.—S. Flexner and P. A. Lewis take up the subject of the possible infectiousness and mode of transmission of epidemic poliomyelitis. They notice the resemblance, as regards distribution of this disease, to cerebrospinal meningitis, pointing out that the relation between group cases in a house or locality has been made out only recently by finding, in the case of meningitis, definite diplococcus carriers, and in poliomyelitis by discovering abortive cases which would seem to act in the manner of microbe carriers. It is held that the diplococcus passes into the cerebrospinal membrane by way of the lymphatics from the nasopharyngeal mucous membrane. It is difficult if not impossible to show in human beings that the diplococcus passes from the membranes by a reverse lymph current into the nasopharynx. This, however, is highly probable and would readily explain the intracellularis infection of these membranes in the disease. In the monkey it has been followed up by the microscope, and the same condition may be readily supposed to exist in man. Flexner and Lewis have studied the mucous membrane of the nasopharynx with reference to the virus of poliomyelitis. The entire mucosa of these parts in monkeys recently paralyzed has been excised, rubbed up with coarse sand pressed through a bacteria-tight Berkefeld filter, and injected in the usual way into the brain of monkeys. In this way the authors have been able to produce paralysis and thus prove that the mucous membrane contains the virus of poliomyelitis. They have also found that when the virus is injected into the spinal canal by lumbar puncture it sets up the disease with its characteristic paralysis. The cerebrospinal fluid removed from monkeys at the onset of paralysis is altered; it contains an excess of protein and lymphocytes and coagulates spontaneously. Paralysis also follows the inoculation of this fluid into the brain. These experimental results show that a path of elimination of the virus of poliomyelitis, as well as of infection, is by way of the nasopharyngeal mucosa. Hence it would seem desirable in the present state of our knowledge to deal prophylactically with epidemic poliomyelitis, as with epidemic cerebrospinal meningitis, by disinfecting and destroying the secretions of the nasal and buccal cavities. The action of disinfecting agents for this purpose is now being studied.

The Lancet, February 12, 1910.

The Variability of the Lesions in Polioencephalomyelitis.—An endeavor is made by Karl Bremer to obtain some idea of the relative frequency of the lesions produced by this disease as it occurs sporadically in and around London. During the last ten years about 400 cases were seen, and of these 48, or 12 per cent., showed some evidences of an encephalitis, and only 11 cases gave evidences of lesions both in the brain and spinal cord. Paralysis of the muscles of the back and neck was generally associated with some other lesion. The diaphragmatic paralysis was unilateral. Paralysis of the sphincters appears to be rare. Incontinence of urine was present in thirteen children over two years of age. Hyperesthesia was a common early symptom. The cases of bulbar paralysis were rare. The seventh nucleus lesion appears to be the commonest form of encephalitis inferior, and this was an important link in establishing the common etiology of polioencephalitis superior and poliomyelitis, as both have been associated with seventh nucleus lesion. The cerebellar cases with acute onset, occipital headache, ataxia and nystagmus, showed a tendency to complete recovery.

Malignant and Nonmalignant Tumors of Bilateral Origin.—W. Roger Williams says that the well-established fact of the bilateral origin of tumors certainly indicates that tumor diseases is something more than the manifestation of a solitary local aberration. There can he no doubt that the activities of the local cells are largely conditioned by the totality of the forces which determine the integration of the whole organism, and the bilateral origin of tumors points to perturbation of these latter forces. Most bilateral tumors originate in early life, many of them being obviously the outcome of gross developmental lesions of ante-natal origin. There are certain acquired morbid conditions which sometimes determine bilateral neoplasia. It is of interest to note that nonmalignant tumors of bilateral origin are even less exceptional than their malignant cogeners. Among the fibromas, striking examples are met with in the disease called "malignant fibroma of nerves," in which over two thousand tumors have been counted in a single patient. The writer reports many instances of bilateral tumors that have appeared in the literature, and states that it is evident that the bilateral outbreak of malignant and other tumors is less exceptional than is generally believed.

The Menopause, Natural and Artificial.—Arthur E. Giles says that the normal menopause is due to the gradual cessation of ovarian activity. In some cases the period may be summed up in a few months and in others may spread over a few years. The ovaries exercise a dual function; they govern the uterine changes that result in menstruation, and they exert a definite influence on the nervous and vasomotor system. Vasomotor incoordination shows itself in spontaneous flushings and heat waves. These vary in heat and intensity from two to three in a day to twenty; sometimes they are slight and transient, and in other cases give rise to discomfort. A recurring increase of the menstrual flow is not a normal sign of the menopause. Irregularity and scantiness are characteristic, but increase of hemorrhage, particularly if repeated, always means organic disease. The menopause is often considered a time of danger; this is not so. At the age of the menopause there is a predisposition to certain diseases, but the menopause in itself is not a cause of disease of any kind. Patients are sometimes told when they have fibroids that after the menopause they will be well; it has been shown by many writers that the menopause is a fallacious hope with fibroids. The one constant symptom of the menopause was heat waves and flushes, and in cases of apparent menopause due to removal of the uterus the incidence of heat waves gives an indication as to when the real menopause supervened. Dr. Giles presents data which show that after the removal of the uterus with conservation of one or both ovaries, cessation of menstruration follows the operation, but heat flushes do not come on for several years afterward. The removal of the uterus often brings about the menopause a good deal earlier than the usual time. The removal of both ovaries with or without the uterus is usually followed by heat flushes a few weeks after the operation. The lurid pictures which have been drawn of the effects of double ovariotomy in unsexing a woman have been very much exaggerated; these women do not become the sexless hypochondriacs and lunatics that they are supposed to develop into. There are manifest advantages in preserving one ovary when the primary consideration of the woman's health allows of this course. In regard to the treatment of the menopause moral treatment is not without its importance. It should be made quite plain that the menopause was not a time of special danger and that the healthy woman has nothing to fear from it. At the same time, any deviation from health should be carefully investigated and treated. A course of ammonium bromide in ten-grain doses three times a day, combined with some bitter tonic, is useful in allaying flushes and nervous irritability.

British Medical Journal, February 5 *and* 12, 1910.

Empyema Treated by Antiseptic Plugging.—In his last eight cases of resection of the ribs, P. Tytler has packed a wound tightly with iodoform gauze, the wound having been placed in the most dependent position. The plug was kept in three or four days and then withdrawn, the patient having been put in the same position to empty the pleural cavity. In the first dressing of a favorable case about a cupful of sanguinolent fluid will be discharged. The plug is renewed and in another three days if all goes well there will be about a spoonful of discharge and the wound may then be allowed to close. The object of the plug is to disinfect the fresh wound after the passage of the pus, to prevent the ingress of other germs so as to avoid a mixed infection and lastly by firmly closing the wound to prevent collapse of the lung, and if much air has entered at the operation to allow its absorption and draw the lung toward the side, thus tending to abolish the cavity. The author believes that certain clinical observations made by him go to prove the resistence of a previous lung complication as a cause, in fact the only cause, of an empyema. An old empyema is very quickly cured by the method he describes. The matter of dressing becomes much simpler. There are great advantages in having the cavity close up quickly. On account of the possibility of a perforation it is better to wait two or three weeks till the lesion of the lung is healed before emptying the pus, unless its removal is urgent when ordinary drainage should be employed.

Futility of the Official Tests for Color Blindness.—T. H. Butler calls attention to the failure of the test in five cases; these showed in order the following lesions: Congenital defect, acquired defect, partial optic atrophy, partial optic atrophy and retrobulbar neuritis, partial optic atrophy, and retrobulbar retinitis, due to alcohol

and tobacco. The author insists that while these men failed on the worsted tests, they would have all been detected by the use of the Eldredge-Green color perception lamp.

Iodine Catgut.—Frederick Edge describes his method of performing absorbable iodine catgut as follows: Catgut, defatted by lying in ether for twenty-four hours, is boiled in absolute alcohol for one hour. It is then laid in a solution made of 1 part of liquor iodi fortis (linimentum iodi) and 11 parts of water for one week. It is preserved in and used from a solution made of 1 part of liquor iodi fortis and 50 parts of rectified spirit.

Foreign Bodies in the Duodenum.—Somerville Hastings reports the case of a girl three years of age who had swallowed a short piece of pencil with a metal extremity. She was admitted to the hospital three days after the accident suffering from diarrhea and colicy pain. The *x*-ray showed a well marked shadow, evidently the metal end of the pencil, about one and one-half inches from the middle line beneath the right costal margin. The child was examined daily with the *x*-ray, but neither constipating food nor purges made any difference in the position of the pencil. At operation the pencil was felt impacted across the gut just at the bend between the descending and transverse parts of the duodenum. It was disimpacted and pushed into the stomach. It was hoped to remove the pencil by way of the esophagus, but that attempt was abandoned and an incision was made through the anterior wall of the stomach. Innumerable cases are recorded both in children and in adults in which the most varied assortment of miscellaneous articles have been successfully cared for by the alimentary tract and passed by the rectum that the rarity with which they gave rise to any serious trouble must appear striking. The screen examination in the case reported seems to indicate that the duodenum of children is more moveable than might be imagined, and it is probable that this part of the bowel is capable of considerable dilatation. The observations of Müller and Exner serve to show that a curved and pointed body will be rotated by the bowel into such a position that it will pass most easily.

The Existence of Living Creatures in the Stomach as the Cause of Chronic Dyspepsia.—W. Soltan Fenwick has collected more than 180 authenticated cases in which lizards, salamanders, frogs, slugs, caterpillars, worms, leeches, beetles, larvæ chrysalides, or maggots were harbored for a time and accompanied by an intractable form of dyspepsia. There is little difficulty in collecting 130 examples of diseases caused by insects in the stomach or intestines. In the vast majority of cases these insects belonged to three of the fifteen natural orders, the *Diptera*, or two-winged flies, the *Coleoptera* or beetles, or the *Lepidoptera*, or butterflies and moths. The eggs of these insects were usually deposited on food, and in this way reached the digestive tract. A wire screen was no protection to meat, as the flies dropped the eggs through the screen. Garden vegetables not thoroughly cleansed and drinking water might also be the means of introducing larvæ. At least twenty-four varieties of beetles and their larvæ have been identified in the vomit or evacuations of persons suffering from symptoms of gastro-intestinal irritation, and more than forty instances may be found recorded in literature. Sometimes many species of the same family or of different families were found in the same individual, mixed with dipterous larvæ, spiders, millipedes, and entozoa. The continued evacuation of these parasites through extended periods of time indicated that they continued to multiply in the gastrointestinal tract. It was quite certain that not only do the eggs of dipterous and coleopterous insects frequently hatch in the human stomach, but that the larvæ may remain alive sufficiently long to permit of their escape into the more hospitable region of the intestines. If this was true of the normal stomach it applied more forcibly when the condition of subacidity was present. In mild cases of internal myiasis a sharp purge was often sufficient to rid the intestines of larvæ and eggs, while in more troublesome forms the administration of thymol, santonine, or other anthelmintics, often appeared to be successful. Beetles were notoriously difficult to kill and require enormous doses of turpentine in order effectually to rid the patient of them. There was no reason to believe that amphibia ever enjoyed a prolonged existence in the digestive tract, however they might be vomited alive after several hours' residence in the stomach, or they might die and be evacuated by way of the rectum. Instances were on record where such creatures had been swallowed or introduced into the vomitus for purposes of deception or to excite sympathy.

Diverticula of the Alimentary Canal of Congenital or of Obscure Origin.—Arthur Keith states that abnormal diverticula of many kinds are found in connection with the alimentary tract, and he annexes a table showing to what extent the various forms are represented in the museum of the Royal College of Surgeons, and also in other museums attached to the various medical schools in London. Retrocricoid diverticula of the pharynx numbered 10; traction diverticula of the esophagus, 12; cysts apparently derived from the esophagus, 6; diverticula of the stomach, 2; pressure diverticula of the duodenum, 12; developmental diverticula of the duodenum and neighboring parts of the alimentary tract, 2; cysts connected with the intestine, 3; pressure diverticula connected with the small intestine, 7; pressure diverticula connected with the great intestine, 7; Mechel's diverticulum, 95, a total of 156.

Berliner klinische Wochenschrift, January 24 and 31, 1910.

A Case of Severe Diabetes with a Favorable Course.—Swart reports a case of a woman of twenty-nine, whom he saw first on February 20, 1908, with the symptoms of approaching diabetic coma. She had suffered from weakness, polyuria and polydipsia for three months. She excreted 495 gm. of glucose in twenty-four hours. There was marked acidosis; the room smelled of acetone, and she was very drowsy. On a strict diet with a little bread the sugar decreased, as did the ammonia. After four weeks, during part of which she received oatmeal, the sugar had completely disappeared and the acetone reaction was negative. During the following year the allowance of bread was increased to 100 gm. without the reappearance of glycosuria, and at the last report, January 12, 1910, she was still sugar free.

Arthritis Deformans Following Typhoid Fever.—Rothschild reports two cases in which following typhoid fever there developed hip joint disease, which ran a course of many years practically without pain which led to a high grade of anatomical lesions of the joints. On the basis of the clinical cause and *x*-ray pictures he made a diagnosis of post typhoid monoarticular arthritis deformans.

Influenza and the Heart.—Ruhemann says that clinical experience has shown that the influenza bacillus may have a very deleterious effect upon a heart which is injured by inflammation, atheroma, or degeneration. It may be either that the influenza bacillus acts on the heart itself, or the toxins produced by it may affect the nerves or the muscles. Healthy hearts seem to be attacked by grippe but little. The author believes that many cardiac deaths of unknown cause may be dependent upon the influenza bacillus. There are many instances of sudden death in cardiacs who are exposed to influenza, either in epidemics or in the neighborhood of sporadic cases.

Münchener medizinische Wochenschrift, January 25, 1910.

On Acute Poliomyelitis.—Beneke has had opportunity to autopsy three cases of acute anterior poliomyelitis, all of which showed the usual pathological condition of the cord. In each case the tonsils were swollen and showed slight exudation. The lumbar fluid showed nothing characteristic. Spinal cord substance was inoculated into rabbits intraperitoneally. From nine to ten days later these became ill and died, without showing any sign of paralysis. A small portion injected intradurally caused illness on the twelfth day, and weakness of the legs. The spleens of these animals showed large numbers of cells containing blood corpuscles and hemosiderin. Inoculation into a monkey produced positive results. The ganglion cells of the anterior horn in the monkey were markedly invaded with leucocytes. All stages of this were found from the invasion of a few cells to the complete destruction of the ganglia and substitution for them of small abscesses. The hematogenous origin of the disease and its minute pathology are considered at some length.

Potassium Permanganate Crystals as a Local Caustic.—Finck says that the caustic action of potassium permanganate upon tissue is due to two factors, the liberation of nascent oxygen and the formation at the same time of potassium hydroxide. The destruction products of the salt are not poisonous and its caustic action is slow and steady. The author has found that application of the dry powdered crystals in excess makes an ideal means of destroying certain pathological tissues as it eats away the abnormal tissue but does not effect the healthy. His method of application is as follows: He takes a piece of adhesive

plaster somewhat larger than the lesion to be treated. In this he makes a hole of such a size and shape that the lesion in the skin and a very small strip of healthy skin around it are visible through the opening. This plaster he applies to the skin around the lesion. On top of this he places from five to fifteen similarly cut pieces of plaster, thus making a well above the lesion. This well is filled to the top with finely powdered potassium permanganate crystals. Over the whole he applies an unperforated piece of adhesive plaster as a cover. Over this he puts a bandage. If the condition being treated is an ulcer, as for example lupus, it is completely destroyed in forty-eight hours. On removing the plaster there is found a dirty purulent detritus, which is washed away. In place of the ulcer there remains a more or less deep crater-like hole whose base is covered with a black mass of manganese dioride and a yellowish eschar. The borders of the wound are clean cut, and the surrounding tissue is neither swollen nor reddened. If the skin is normal a drop of water is added to the permanganate and the plaster is left in place from four to six days. The destructive process goes on either without pain or with but a slight burning, the latter especially when applied to the normal skin. The after-treatment is simple. The wound is dressed dry or with an ointment. The next day vigorous granulations appear, which replace the eschar and in a few days fill the hole. The scar is smooth and contracts or hypertrophies but little. The method may therefore be used on the face. It may be applied to any lesion of any size or depth. The author has used it especially for chancroids, fungus, granuloma, decubitus, ulcus cruris, angioma cavernosum, keloid, and carbuncles. It is also indicated in small tumors of the face, nevi, angiomata, lipomata, papillomata, etc. If the tumor is subcutaneous, the hole in the plaster must be made smaller than the apparent size of the tumor. Children's skin is attacked most easily; that of the extensor surfaces of adults resists most. The author also uses potassium permanganate crystals in tuberculous bone and joint fistulæ. He has a tube 6 mm. in diameter and 5 to 10 cm. long with a funnel shaped top and a plunger. This is inserted into the fistula to the bone, and with the plunger the wound is tightly packed with powdered permanganate, slowly withdrawing the tube as the packing is done. There is on occasion severe pain which lasts in the neighborhood of one hour. After one to two days the mass begins to be discharged, often with it coming bits of blackened sequestrium. This treatment often results not only in the closing of the fistula, but in the healing of the tuberculous process. If healing does not occur after one treatment the process is repeated. The method is contraindicated in fresh fistulæ with abundant secretion and in fistulæ close to large vessels and nerves.

Deutsche medizinische Wochenschrift, January 27 and February 3, 1910.

Acute Yellow Atrophy Following Resection of the Liver.—Rinne reports a case of a woman of thirty-three years of age on whom he did an exploratory laparotomy for a tumor in the right side, pain, and vomiting. The operation showed a syphilitic liver with a large lappet, extending down into the abdomen, and connected with the liver by a pedicle three fingers' breadth in diameter. This was resected by the thermocautery and the base ligated with a series of deep stitches. The patient recovered well from the operation, but on the fifth day became restless and confused and showed a slight jaundice. The next day the symptoms increased, she became unconscious, and on the eighth day she died in coma. The urine was bile stained and contained casts, but no leucin or tyrosin. The autopsy showed the characteristics of acute yellow atrophy on the basis of the old leutic lesions. The anesthetic consisted of scopolamine and morphine, with a very little ether. No chloroform was used. There was no wound infection and but slight hemorrhage. No poisonous disinfectants were used inside the abdomen, and the packing was simple sterile gauze. Cases of yellow atrophy have occurred associated with syphilis. One case of acute yellow atrophy has been reported following resection for ecchinococcus cyst. The exact cause of the condition in this case cannot be explained unless it is the result of the resection.

The Treatment of Chronic Cardiospasm.—Elsner describes the various instruments used for dilating the cardiac orifice of the stomach in cases of cardiospasm, laying especial stress on Gottstein's spindle shaped balloon. He says, however, that in certain cases the esophagus is so dilated and the spasm so tight that this does not go through into the stomach. He then describes his own modification of the Gottstein instrument which consists in inserting a metal tube down the middle of the rubber tube and balloon, projecting a short distance below the latter. The purpose of this is that by aspiration of stomach contents one is able to be sure that the balloon is in the cardiac orifice.

Tuberculin Treatment with Large Doses.—Neumann says that it may be considered as proved that in general children can stand much higher doses of tuberculin than have previously been used. In a large number of children the original sensitiveness to tuberculin was lost relatively quickly, and one had to inject larger doses in order to obtain perceptible results. In respect to the most effective method of using tuberculin more experience must be collected, and for this purpose the significance and the course of the local puncture reaction must be more thoroughly studied than appears to have been done before.

The Intramuscular and Intravenous Use of Large Doses of Diphtheria Antitoxin.—Berlin discusses his experience with antitoxin in the Augusta Hospital in Cologne. Though in recent years the mortality had sunk from 30.9 per cent. to 17.5 per cent. in diphtheria, he was not satisfied and increased the doses of antitoxin and also gave them intramuscularly and especially intravenously. For this purpose he injected serum preserved in a little carbolic acid, in quantities of 8 cc., equivalent to 4000 units. The amounts injected varied from 4,000 to 16,000 units. When the intravenous injection was given in 62 cases there was striking improvement; in 34 the temperature dropped to normal on the first day, and in 28 it sank more gradually, but was normal on the second day. An especial influence upon the local symptoms in the throat could not be determined. Of 67 cases of pharyngeal diphtheria 2 died, of 37 cases of laryngeal diphtheria 11 died, and of 16 cases of septic diphtheria 10 died. No untoward symptoms were observed as a result of the intravenous use of the serum. The point of injection showed no reaction, only once was there a small thrombosis, which quickly disappeared. No kidney lesions, which might have been expected from the carbolic acid injections were observable. In eight cases there was marked urticaria. In a few cases there was a slight rise of temperature on the seventh to the ninth day. Associated with a general glandular enlargement, Berlin draws the following conclusion: (1) The favorable influence of large doses of serum, up to 16,000 units, cannot be doubted; (2) intravenous or intramuscular injections produce a more rapid action than subcutaneous; (3) the large doses of serum, even combined with carbolic acid, are harmless.

Bronchiolitis Obliterans Following Diphtheria.—Colombino reports the case of a woman of twenty years who, as a sequence of a severe diphtheria, and paralysis during convalescence, developed a typical bronchiolitis obliterans. He is not able to state whether the bronchiolitis was caused by direct injury to the walls of the bronchioles by the diphtheria or whether it was the result of the bronchitis brought on by the paralysis of the muscles of deglutition.

The Danger of Narcosis with the Artificially Decreased Circulation.—Gräfenberg reports his experience in operations with decreased circulation produced by tightly bandaged legs. Of 75 laparotomies performed 6 were followed by thrombosis. These results led the author to discontinue the use of the method.

The Significance of the Treponema Pallidum in the Diagnosis of Syphilis.—Scholtz says that the discovery of the treponema has been a great advance in the diagnosis of syphilis. They are so regularly found and so easily seen in the eroded specific eruptions of the primary and secondary period, in primary sores, eroded papules, condylomata, and mucous patches that they are of the greatest aid in practice. There are three chief methods of demonstrating the treponema, the staining with Giemsa's stain or its modification, the dark field microscope, and the India ink method. The Giemsa stain colors the parasite so dimly that it is difficult for the untrained eye to distinguish it and differentiate it from other spirochete. The dark field microscope is a quick and accurate means of diagnosis, but it is available only to a few. The India ink method is simple and good. The fresh material for examination is mixed with India ink and the mixture is spread very thinly on the slide. The background becomes a homogeneous brown or black under the oil immersion lens, and the spirochetes shine through as colorless refractile bodies. The author has found this method as accurate as the dark-field microscope. The technique used by him consisted in taking a tiny drop of serum from the lesion, a similar drop of water, and a third one of ink. After these are mixed well they are spread with the edge of another slide.

Book Reviews.

A Textbook of Physiology: For Medical Students and Physicians. By William H. Howell, Ph.D., M.D., LL.D.; Professor of Physiology Johns Hopkins University, Baltimore. Third Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1909.

The publication in so short a time of three editions of this textbook is made necessary, according to the author, by the rapid strides which have taken place in the science of physiology. The book is written primarily for medical students, and the author confines himself in consequence to what is either proven or generally accepted as fact, keeping away as much as possible from controversies, and not allowing himself to be drawn into confusing discussions. Where several theories are advocated, the most acceptable one is usually given in full, and then in many instances the others are cited in brief and in smaller type. Two most valuable features are the frequent appearance of brief summaries, giving clearly the important and essential points of the more lengthy physiological discussions and explanations, and a fairly complete system of references, particularly to the newer literature, enabling the student to delve more deeply into any subject in which he may become especially interested. The book is of a more convenient size than many medical books, is well printed, in large, clear type, on good paper, and is profusely and excellently illustrated. The new edition of the book will maintain the reputation of the two earlier ones.

Traitement de la Syphilis. Par le Professeur Alfred Fournier. Third Edition. Paris: Vigot Frères, Éditeurs, 1909.

Fournier's classical work on the treatment of syphilis now appears in its third much augmented and revised edition. It contains everything appertaining to the subject matter chosen, from a discussion of the necessity of treating syphilis to the latest methods, preparations, and general régime of mercurial therapy. The subject is treated in such detail that no questions whatever remain in the mind of the reader after perusing the book; every method of treatment, whether supported or opposed by the author, is considered with ample discussion of the reasons brought forward by the defenders of these methods. The most important part of the book, however, is concerned not with syphilis itself, but with the host of parasyphilitic affections, the occurrence of which is considered by the author the dangerous feature *par excellence* of the disease, for the usual treatment adopted far and wide does not take into consideration the late and invidious appearance of lesions in the internal organs and in the nervous system. Complementary cures and general hygienic régime are emphasized as the only means so far available in the prophylaxis of these late sequels of syphilis; the authority of the author, and the wealth of experience drawn upon claim such attention as no other man's work in the matter can at present enjoy.

Recent Advances in Physical and Inorganic Chemistry. By A. W. Stewart, D.Sc.; Lecturer on Organic Chemistry in the University of Belfast; formerly 1851 Exhibition Research Scholar and Carnegie Research Fellow. With an introduction by Sir William Ramsay, K.C.B., F.R.S. With diagrams. New York, London, Bombay, and Calcutta: Longmans Green & Co., 1909.

This is not a textbook on chemistry, but rather a series of essays on various special topics connected with that subject; it thus constitutes a departure from the old methods of book writing. It deals, for the most part, with researches which have been made within the last twenty years, but the time limit is not rigidly adhered to. The subjects discussed are all of them important, and are as follows: Some hydroxylamine derivatives; colloids; reactions in liquid ammonia; the fixation of nitrogen; double salts; the problem of the oceanic salt deposits; the cobaltamines; absorption spectra; the elements of the rare earths; atomic weights; the inactive gases; the radioactive elements, radioactive changes, and radioactive emanations. The author presents rival theories with impartiality, but at the same time he does not hesitate to express his own views. He is always fair, and always readable. In his all too brief introduction, Sir William Ramsay compares the author to a skilful cook, who has trimmed his joint, rejected all innutritions and redundant excrescences, and has served it up to table in a palatable form. There can be no doubt of the importance of chemistry to medical men, and these eminently readable essays will do more to encourage a taste for chemistry than will many textbooks.

The Practical Medicine Series. Comprising ten volumes on the year's progress in medicine and surgery. Under the General Editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume VIII. Materia Medica and Therapeutics, Preventive Medicine, Climatology. Edited by George F. Butler, Ph.G., M.D.; Henry P. Favill, A.B., M.D., and Norman Bridge, A.M., M.D. Volume IX, Skin and Venereal Diseases. Edited by W. L. Braun, M.D., and Harold N. Moyer, M.D. Chicago: The Year Book Publishers, 1909.

About two-thirds of Volume VIII is devoted to materia medica and therapeutics. In this section the drugs and other therapeutic agents are arranged alphabetically. In the section devoted to preventive medicine are discussed the prophylaxis of disease, the health laws, and police power for their enforcement, *et cetera*. The book ends with a few pages devoted to the subject of climatology.

Volume IX is divided into two sections. The first deals with skin and venereal disease, and the second with miscellaneous subjects, such as heredity, smoking, alcoholism, the physician and the press, and proprietary medicines.

The Practice of Anesthetics. By Rowland W. Collum, L.R.C.P. Lond., M.R.C.S. Eng.; Anesthetist to St. Mary's Hospital, Paddington, the Charing Cross Hospital, and the Hospital for Sick Children, Great Ormond Street; and General Surgical Technique. By H. M. W. Gray, M.B., C.M. Aberd., F.R.C.S. Edin.; Surgeon and Lecturer on Clinical Surgery Royal Infirmary, Aberdeen. Edited by James Cantlie, M.A., M.B., C.M. Aberd., F.R.C.S. Eng.; Surgeon Seaman's Hospital Society; Lecturer on Surgery, London School Tropical Medicine; Surgeon West End Hospital. New York: William Wood & Company, 1909.

The first part of this book is on anesthetics. The author first considers the chemical properties and impurities of the chief anesthetics, nitrous oxide, ether, chloroform, and ethyl chloride. He then discusses the physiology of anesthesia, and shows the effects of these anesthetics on the respiratory, circulatory, nervous, and muscular systems. The next chapter shows in detail the preparation of the patient. This is followed by a very complete discussion on the selection of the anesthetic, and procedure in special cases; the condition of the patient and the nature of the operation are both considered at some length in this connection. Then follow sections describing the administration of each anesthetic; there is a short chapter on mixtures and sequences; and this is followed by two important chapters on difficulties and dangers and their treatment, and on after effects and their treatment. The whole subject is handled in a masterly way; it is written for practical use by one who has enjoyed a very large experience as an anesthetist and who knows exactly what students require. The style is clear and forceful, and the print, illustrations, and general get-up are all attractive. The last half of the work is on general surgical technique; it, too, is of much value, and contains many details and minor points which are of importance, but which are often omitted in larger works.

Primer of Sanitation. Being a simple work on disease germs and how to fight them. By John W. Ritchie, Professor of Biology, College of William and Mary, Virginia. Illustrated by Karl Hassmann. Yonkers-on-Hudson, New York: World Book Company, 1909.

In this little volume the author has been wonderfully successful in presenting in simple language the more important facts in regard to germ diseases and their prevention. It is well adapted to serve as a textbook for the pupils in our public schools; and it would be difficult to find a book better adapted to interest the young, and at the same time to benefit the whole community.

A Book of Quatrains. Original and Translated. By Frederick Rowland Marvin. Boston: Sherman, French & Co., 1909.

Dr. Marvin, who though a physician labors in the Ministry, finds respite from professional toil in the delightful pursuit of the poetic muse. Many of these verses were written in odd moments and reflect the varying moods of one who has watched the panorama of human life with curious and observant eye. There are also a number of translations from the Persian, Arabic, Greek, and Roman anthologies, and from the more modern French and German. It is impossible to quote at length, but the following is a fair example:

Our friends, as years advance, depart,
But noble books remain;
In them the blessed dead return,
To dwell with us again.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 3, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Orthopedic Surgery.

A Case of Fracture-Dislocation of the Upper Cervical Vertebra Complicating Spinal Pott's Disease.—Dr. FRED H. ALBEE presented a woman, twenty years of age, who gave a tuberculous family history, one sister dying of this disease. She stated that in December, 1906, she caught cold and had a stiff neck for two weeks; she was able, however, to continue at her work at the end of this time. While returning to her home she was run into by a man and her head, so she claimed, was hurt, so that she was compelled to support it all the way home. She was then confined to her bed for three weeks. She held her head constantly with her hands. When she was examined it was found that the cervical spine had lost its normal contour, and that the head was in a position farther forward than was normal, and the spine was fixed in that region. A plaster jacket was applied and the head supported. In November, 1907, although the pain complained of was relieved, she could not hold her head without support, and there was found a prominence of the postpharyngeal wall. The head support was continued for some time, only being taken off one year ago. During the past year the patient had been at work and without any trouble with her neck whatever. The movements of the head, including rotation, were good at the present time. The *x*-ray showed a dislocation of the upper cervical region, and now the reparative process. Later skiagraphs showed an almost complete destruction and absorption of the body of the axis and an agglutination of the upper three cervical vertebræ. There had been no signs of paralysis at any time. The knee jerks had been somewhat exaggerated.

The Differential Diagnosis Between Torticollis and Other Causes Producing Deformity of the Neck.—Dr. REGINALD H. SAYRE opened this symposium on certain surgical conditions of the neck. Torticollis was generally recognized as a deformity of the neck caused by irregular muscular contraction. There were, however, a great many causes which might cause the neck to be distorted. Although the origin of these deformities varied, in many instances there was more or less difficulty in making a diagnosis of one from the other. Torticollis might be either congenital or acquired. He believed that quite a large number of so-called acquired cases of torticollis were in truth cases of congenital torticollis with the deformity so slight at the time of birth that attention had not been called to it. But as the child grew the deformity showed itself, showing a unilateral increased growth. There were a number of causative factors in the production of torticollis. In the congenital form a lack of amniotic fluid was given as a cause by some; by others, pressure against the pelvic walls. There was evidently something in the makeup of the embryo which gave rise to a distortion of the cervical spine in quite a number of cases, as they found a fusion of the cervical vertebræ, and sometimes there were found supernumerary vertebræ, as well as other deformities of the cervical spine. A lateral curvature of the spine might take place in either the cervical, dorsal, or lumbar region; in all these cases it would be found that the spine was twisted. Some of the cases of torticollis came from some congenital defect in which there was produced a malformation of bone. In some cases there was some lesion of the central nervous system which produced an unequal bone growth on the two sides of the neck. There were many acquired cases in which the formation of a hematoma of the sternocleidomastoid muscle at the time of birth, was claimed by some as the causative factor, but Dr. Sayre believed that it was erroneous, as observations had shown that many hematomata disappeared leaving no traces and that many contracted muscles were not preceded by them. There was not a contraction of this muscle, but a failure to grow and the torticollis was caused by the muscle of one side growing when the other did not. Again torticollis was found to follow burns of a severe character; the contractions drew the head down. There were some cases that were believed to have occurred idiopathically. Why should these muscular contractions occur? There must be some central defect of the nervous system. Occasionally one met with some central paralysis in these cases. Dr. Sayre presented many pictures of patients suffering from torticollis and from cervical inflammations resembling it, as well as some *x*-ray photographs. Some of the cases resulted from metastases, some from infected tonsils, middle ear disease, fractured vertebræ and upper cervical tuberculosis, etc. These were not cases of true torticollis, however, and could be eliminated from that category by a careful questioning. Whenever a patient had pain, elevated temperature, or muscular spasm, which was similar in character to what was met with in the spasm of an inflamed joint, then one should not make any mistake in the diagnosis, as all these cases were due to bone inflammation and not true torticollis.

The Theory, Technique, and Results of Psychomotor Reeducation in Convulsive Torticollis.—Dr. RICHARD B. KRUNA read this paper. He said that the grouping of convulsive torticollis under the heading of "convulsive tic" had been agreed to by such neurologists as Landois, Dana, Brissaud, Oppenheim, Meige, and Feindel and this pathological view gave direction to the therapeutic efforts termed "Psychomotor Reeducation." The volitional centers were the seat of this disorder. The automatic impulse and its motor expression repeated themselves with or without intermissions. Sometimes they could be regulated by some psychic control still persisting, but this happened only under exceptional circumstances. A complete examination of a case of convulsive torticollis would determine what part of the automatic impulses had become abnormally free from the inhibitive and which one independent of the initiative. The loss of initiative might be partial or total and the corresponding motor-elements would be found partially or totally missing. The disorder of connection between the conscious volition and its execution through the corresponding muscles could assume different variations. The ultimate purpose of treatment had to be the strengthening of the two factors of the patient's volition, the initiative and the inhibitive. There were two methods of approach to this: First, an educative effort directed toward the patient's mind, stimulating and testing in a methodic prolonged training his stamina of character, teaching him for hundreds of days to refrain from extremes of emotion, bringing his daily life, by exhaustive planning, to the regularity of clock-work. To follow this minute plan, in itself, offered a wealth of daily tasks and tests for the patient's ability to stop and to begin, to follow his duty, not his inclination. The second method aimed at the reeducation of conscious volition by psychomotor reeducation proper. This training consisted in courses of exercises requiring the use of conscious volition and conscious motor acts. However simple these exercises appeared to the healthy they offered a vast field of difficulties and problems to the patient. The motion elements necessary in the work were: (1) Rotation of the head on the sagittal axis; (2) rotation of the chin alone on the sagittal axis; (3) rotation of the head on the vertical axis; (4) rotation of the head on the frontal axis; (5)

rotation of the chin alone on the frontal axis (elevation and depression). The starting point was to determine what motor elements were totally or partially absent and the purpose of the exercises was to restore these elements. The next step was an examination of the motion complexes in which the motion elements, which individually had been lost, were preserved. These motion complexes were the material upon which to work in the first group of exercises. At first the conscious volition would not be successful in effecting the desired muscle contraction or contractions. A repetition of this act of initiative in spite of its lack of external results in the beginning, if prolonged over the necessary period of time, varying from weeks to months, eventually resulting in fractional movements, irregular in frequency and extent at the start, but becoming increasingly regular and more extensive with exercise. After reestablishing initiative control of the automatic action of the motion elements formerly lost the attempt was made to reestablish the inhibitive control of the tic movements which were pathologically independent. This might be done by a group of exercises of immobilization. Meige and Feindel advised patients to assume attitudes and maintain them with perfect immobility. The exercises of immobilization, graded according to their difficulty were: (1) Immobilization of the head with the shoulder girdle fixed; (2) immobilization of the head with mobilization of the shoulder girdle; (3) in the same manner immobilization of the head and neck was to be combined with immobilization exercises of the trunk then with mobilization of the trunk, and finally with immobilization and mobilization of the legs. The conquest once made it had to be maintained by a continuation of the same efforts, and perseverance for a number of years ultimately made the performance of the motion element automatic. As to prognosis, two classes of patients presented themselves, one in which excessive physical and psychical had led to the deformity, the patient's constitution being previously sound, and, a second class, those in whom the torticollis was superimposed on a constitution previously faulty; the local prognosis was mostly dependent on the general one. From a few weeks or months in psychomotor reeducation as little could be expected as in any other branch of education where permanent and complete results were required.

Displacement of the Upper Two Cervical Vertebræ Without Immediate Symptoms of Cord Compression.—Dr. Robert R. Osgood of Boston read this paper. The reader of this paper and Dr. Samuel J. Mixter had undertaken a study of the traumatic lesions of the atlas and axis in the course of which many interesting displacements were discovered. The significance of certain of these lesions lay in the fact that they were commonly nonfatal in their early stages and that their successful treatment depended upon their accurate diagnosis. The extreme degree of displacement which was in certain cases consistent with life, liberty, and pursuit of happiness was most surprising. Dr. Osgood described accurately the anatomy of the upper two cervical vertebræ and exhibited lantern slide illustrations. He showed that at the atlantoid joint there was forward and backward and a little sideways motion, while at the atlo-axoid joints there were turning motions, the head rotating with the atlas. Attention was called to the fact that, in order to allow the free motions of the head, the ligaments were all lax, and that the head must be held firm by muscular action alone. If this muscular support was lacking any blow found a condition conducive to the production of a dislocation or its complicating fracture. The posterior roots of the cervical nerves, from which branches the three chief occipital nerves, were much larger than the anterior, and by their connections with the pharyngeal and cervical plexus, and through this with the brachial, explained the referred symptoms accompanying these injuries. The commoner displacements were first considered as well as their method of production. No case had been reported in which recovery took place after complete isolated dislocation of the occiput on the atlas. Rotary dislocations of the atlas on the axis were not very common and were usually bilateral, owing to the shape of the articular processes and the laxity of their capsules. Complete bilateral dislocations of the atlas on the axis occurred without immediate fatal consequences though they were, however, rare and usually associated with complicating fractures. The simplest and by far the commonest displacement was a unilateral dislocation of the axis on the third cervical vertebra. Here, owing to some traumatism or even to the sudden contraction of a muscle group alone, one of the inferior articular facets of the axis slipped upward and forward, either impinging upon the superior edge of the articular process of the third or slipping forward into the notch in front. This lesion was, of course, not confined to the axis, but might occur in any of the cervical vertebræ. There was usually no fracture and the condition might be spoken of as a subluxation. These were the cases that often were spontaneously reduced during the administration of the anesthetic and by quick unguarded movements of the patient, although they not rarely resisted all but appropriate manipulation, especially if the lesion was one of long standing. The bilateral dislocations of the axis on the third were rare and the picture was similar in many respects to the bilateral dislocations of the atlas on the axis, though more difficult of reduction, owing to the shape of the articular processes. Cases were cited illustrating these various dislocations. Fractures of these two upper vertebræ presented more difficult, though, fortunately perhaps less frequent problems. Because of the apparent rarity of these fractures the reader reported a case. Fractures of the axis were far more common, because the laminæ were more exposed and the spinous process quite prominent. Certain of the football injuries of the past season might possibly have included the second vertebra. By far the most important fracture of the axis was the fracture of the odontoid process and it was to these fractures and to the displacements which followed that attention was especially directed. Out of twelve cases of isolated fracture of the axis reported by Dr. Van Assen in nine, or 75 per cent., the odontoid alone was broken. There was evidence to show that union of the odontoid, if it occurred at all, was fibrous only. Cases in which this lesion occurred formed a most interesting group, both in their immediate and subsequent histories. The displacements due to disease in which there was an apparent solution of continuity of the odontoid and a slipping forward of the atlas and occiput on the axis were quite as remarkable as those entirely due to traumatism. The amount of departure from the normal position which was compatible with life and was productive of no paralytic symptoms was amazing. He cited a case to illustrate this and also one that illustrated that the axis could be displaced far forward without symptoms of cord pressure. The immediate symptoms which followed these lesions varied from almost instant death to an entire absence of all symptoms except neck rigidity and asymmetrical head position. The striking phenomenon was the frequency with which only comparatively slight symptoms resulted. Severe occipital neuralgias and neck rigidity with increase of pain on any attempted active or passive movement of the head were nearly always present and should lead one to suspect bony lesion. The rigidity and neuralgia usually persisted, and sudden movements or attempts at reduction were often followed by immediate fatal consequences, but the most important end result was the gradual onset of a myelitis apparently caused by the irritation of the long continued abnormal position or, in the case of fractures,

by callus formation. The accurate diagnosis of these conditions was obviously of much importance. Lateral *x*-rays of the neck presented no special technical difficulties and showed well any anteroposterior abnormality and often suggested a lateral asymmetry in a dislocation. The ordinary anteroposterior *x*-ray of the neck was valueless as far as the atlas and axis were concerned. A skiagraph taken through the open mouth often gave important information. Odontoid fractures might be seen and any lateral displacement demonstrated. When good *x*-rays were not available much might be learned by inspection and palpation. Inspection revealed the probable displacement if one reasoned out the lesion necessary to produce the individual asymmetry. In the unilateral dislocations the chin would almost without exception point to the side opposite the lesion. By palpation one might discover many things. The value of the examination of the pharynx, preferably under an anesthetic, could scarcely be overestimated. In spite of these helps it was difficult to determine positively the integrity of the odontoid. The importance of this determination was made apparent by several cases in which the penalty for what proved to be unintelligent manipulation was the life of the patient. If one could convince himself that a simple unilateral rotary dislocation of the atlas or axis had occurred intelligent manipulation offered every hope of cure. Walton's method was the only rational one. This consisted of first freeing the dislocated articular facet of the upper vertebræ from its position. Whether this upper articular process had simply caught on the apex of the process of the vertebra below or actually slipped forward into the anterior notch was a difference only of degree. It should be lifted free, then rotated into place by the manipulation of dorsal lateral flexion followed by rotation. In doubtful cases he advised support and fixation by means of apparatus until a definite diagnosis had been made. None of the authors that he had consulted considered operative procedures possible, so it was with much modesty that he ventured to describe an operation at which he had assisted Dr. S. J. Mixter. The case was a boy of fifteen whom they had treated for some time before a fracture of the odontoid was suspected. The boy was put to bed with head extension. A leather cuirass in two pieces was made from an accurate cast taken by laying the patient in a bed of soft plaster and then making the anterior half by pouring over the chest and neck thin plaster cream. When this accurately fitting apparatus was ready the following operation was performed: The boy was placed in the ventral position, the head being supported manually over the end of the table. A linear, four-inch incision was made in the median line of the neck and carried down until the hooked spine of the axis was defined. The posterior arch of the atlas forwardly displaced was sought and exposed. With an aneurism needle a stout braided silk soaked in compound tincture of benzoin was passed about this posterior arch between it and the spinal cord. While forward pressure on the anterior arch was exerted through the pharynx traction was made on the posterior arch. There was firm resistance to replacement and only a slight amount of reposition was accomplished. This was maintained and the atlas firmly anchored by tying the silk band about the hooked spinous process of the axis. The wound was closed with deep silk worm gut sutures, and the leather cuirass applied and strapped tight. The wound was dressed through a posterior window. The boy made an uneventful recovery with no paralytic symptoms and an absence of pain and up to the present had remained well and led an active life. It was now two and one-half years since the operation.

Dr. Virgil P. Gibney said that most of us looked upon the congenital cases of torticollis as due to a hematoma of the sternocleidomastoid muscle occasioned during the delivery of the child, and that the physician in attendance should see that this hematoma was disposed of promptly as the slow process of resolution left connective tissue in the body of the muscle. Later when the child grew older the muscles failed to develop symmetrically and torticollis resulted. Dr. Osgood's paper was full of practical suggestions and thanks were due him for demonstrating so graphically these distressing fractures and subluxations in the upper cervical vertebræ. The most distressing forms of torticollis occurred in hysterical women when there was the rotatory spasm along with it.

Dr. Leonard W. Ely said that Dr. Osgood's paper was particularly valuable because it contained an account of a fractured spine cured by operation. In reading up the writings of others on the subject one could not but be impressed by the hopelessness of operation. Even those who advocated operation published results that could deter one from operating. During the past year he had seen two cases of subluxation of the axis on the atlas, one being complicated with paralysis, the other not. One of these cases, a boy, had fallen and showed the typical picture of such an injury; he was completely paralyzed and had to be lifted from his bed and swung up to have a Calot jacket applied. In the course of a few weeks his condition improved so that he could get about the wards of the hospital. Two months after its application the jacket was removed and then the paralysis came on and was worse than it had been before. The jacket was then again applied, and he again improved so that power in legs and arms was almost normal. He was now at his home. Dr. Ely believed that if the jacket was now removed, he would go back to his condition of paralysis. In this case the paralysis could not be due to callus formation, for it disappeared almost immediately both times the jacket was applied.

Dr. William M. Leszynsky said that malposition of the head simulating torticollis, and due to an affection of the eyes as mentioned by Dr. Sayre, was usually caused by defects in the ocular muscles and not from a refractive error. In such cases, the deformity resulted from the patient's efforts to obtain binocular single vision. He had seen several cases of this character. In one there was a congenital defect involving the action of one external rectus muscle. The type of torticollis cases referred to by Dr. Sayre, and so commonly seen by orthopedists, differed essentially from those seen by the neurologist. In the former, there was a tonic form of spasm secondary to vertebral disease, while in the latter the spasm was usually of the clonic variety and of neurotic origin. This was most frequently classified to-day as a localized convulsive tic. In its initiatory stage it was merely an exaggerated volitional movement, and ultimately these movements become automatic and uncontrollable. This was the type which under ordinary conditions proved so persistent and intractable. The longer its duration the more resistent it was to treatment. Absolute rest in bed for a time was essential in many cases. The hypodermic injection of atropine in increasing dose into the affected muscles had in some instances effected a cure. Some years ago Dr. Leszynsky reported several successful results, and enthusiastically advocated this plan. Since then, with longer experience, he had concluded that while the atropine treatment proved exceedingly beneficial, nay, even curative in some cases, it was unsatisfactory in many others, and should be considered only as an adjuvant to absolute rest and general management. A light head-brace might be worn with comfort as a supplement to other treatment, but the majority of patients could not tolerate it. Surgical measures such as division of muscles and nerve resection had been disappointing. Dr. Leszynsky had reported in 1900 two successful cases treated by exhaustive massage of the affected muscles in conjunction with methodical active and passive movements of the head. Psychomotor

reeducation was the ideal method of to-day, and Dr. Kruna was to be highly commended for having brought this matter to your attention in such a lucid manner. This plan required the intelligent cooperation and perseverance of the patient. Hence, it is necessarily limited in its application. However, if it could be satisfactorily followed, the outlook for these sufferers was most encouraging.

Dr. Charles Dwight Napier reported a case of fracture of the odontoid process seen in a patient eighteen years of age. The boy fell from a tree one year before the doctor saw him. He was told that after the fall he got up and walked to his home; he suffered from rigidity and pain in the head and a lateral bending, but he had no other symptoms. He was untreated until about five months after the accident; then there ensued a paralysis. One year after the injury he came under observation with paralysis, a syringomyelia, probably due to interference with the lymphatic circulation of the cord because of the pressure. In the arms and legs he had but little power. After a time he improved under head extension and today, having been in bed for six months, he had complete power. The *x*-ray plates showed that he had a fracture of the odontoid process. Dr. Napier thought that this was a case that might have been benefited by the operation described by Dr. Osgood.

Dr. Sayre said that he had tried to control the convulsive movements by the administration of gelsemium and conium; he had quieted these patients, but only by giving such doses of these drugs as nearly quieted the circulation. The tics ceased while they were administered in these doses: when he omitted the giving of these agents, the symptoms all returned. His operative experience in these cases had not been at all favorable; the division of the posterior cervical nerves had not resulted in benefit.

SECTION ON MEDICINE.

Stated Meeting, Held January 18, 1910.

Dr. C. N. B. Camac in the Chair.

Pernicious Anemia; Marked Improvement Following Large Doses of Hydrochloric Acid.—Dr. Julius Rudisch reported this case. The past history of the case presented a few points of special significance. The patient was a woman, forty-six years old, a Roumanian. Since her menopause three years ago she had gradually lost weight; there was also a marked anorexia. Five days before her admission to the hospital, October 30, 1909, she fell upon the pavement and sustained a fracture of the left leg. Besides the fracture it was noticed during the physical examination that she was markedly anemic, emaciated, with a waxy pallor of the skin. A short systolic murmur was present over all the cardiac orifices, which was regarded as functional. An examination of the other thoracic organs, as well as the abdominal, gave negative results. The blood examination at the time of her admission showed 1,880,000 red blood cells, 11,400 leucocytes, hemoglobin 30 per cent. The differential count showed 44 per cent. polymorphonuclears, 41 per cent. small lymphocytes, 6 per cent. large lymphocytes and 9 per cent. large mononuclears. There were also noted a marked poikilo- and anisocytosis, many macrocytes, and a few normo- and megaloblasts. The picture was, therefore, one of typical pernicious anemia. A test meal revealed a total acidity of six, with no free hydrochloric acid. The subsequent test meals, the last only the day before this report, gave practically the same results. The urine had from time to time contained a faint trace of albumin and a few hyaline casts. An examination of the feces showed no parasites or ova. Ten days after admission the hemoglobin fell to 20 per cent. following a severe epistaxis with bleeding from the gums. The blood findings remained otherwise unchanged. One week later a marked granular degeneration of the red cells was noted, and from this time on the hemoglobin gradually rose during a period of three weeks to 45 per cent., although the macrocytes and nucleated red cells did not disappear. A subsequent examination of the blood, however, showed a gradual disappearance of these abnormal cell varieties, with a progressive increase in the number of erythrocytes, and in the amount of hemoglobin. Dr. Rudisch said he would omit all the examinations made of the blood count except the one made two days ago. At this time the red cells numbered about 3,250,000 and the leucocytes 5,000. The percentage of hemoglobin had risen to 61. The differential count had not been notably altered. Poikilocytosis was still present, but in other respects the blood cells were normal. The increase in the weight had been about nine pounds. The great majority of the cases of pernicious anemia suffered from an absence of hydrochloric acid and pepsin in the gastric secretion, but it was further harmful in that the essential element for pancreatic secretion, the secretin, was produced only under the stimulus of the acid chyme passing over the duodenal mucosa. To cause an artificial digestion, pancreatic as well as gastric, Dr. Rudisch therefore administered hydrochloric acid and pepsin in much larger doses than were usually considered permissible. The patient had received 30 grains of pepsin and 105 minims of dilute hydrochloric acid three times a day, the latter being given in 15 minim doses every ten minutes in albumin water to disguise the taste. The fact that the acid was given combined instead of free did not affect its action. The further treatment consisted in daily irrigations of the colon and a liberal mixed diet. It would be seen that, from the blood examination, the treatment had been followed by most satisfactory results.

Dr. Beebe said he was very much interested in the report made by Dr. Rudisch, because he had used a method almost identical with it during the past two years. The report of his work was read before the American Medical Association in Atlantic City last year. In that report he gave the findings and reviewed the treatment employed in nine cases. He thought it was yet open to debate as to whether the administration of the hydrochloric acid was such an important factor in the improvement of these cases. It is well known that the gastric secretion in cases of pernicious anemia was often entirely lacking in hydrochloric acid. The recent advances in the knowledge of the physiology of digestion had demonstrated the very great importance of hydrochloric acid, both in the stomach digestion and likewise as a factor in setting into action a train of mechanisms which were mostly of purely chemical nature, and which facilitated the physiological action of the remaining portions of the digestive tube. It had long been believed that a considerable part of the pathological factors in cases of pernicious anemia might be caused by a toxemia, and if the digestive functions were not under proper control the possibility of an intestinal toxemia would appear to be much greater than under normal conditions. He recalled a case similar to the one cited by Dr. Rudisch, the patient being at the Mt. Sinai Hospital about a year ago, under the immediate care of Dr. Strauss. Large quantities of hydrochloric acid were given to this patient over a considerable period of time, but as far as could be determined it had no beneficial effect whatsoever. Since the report at Atlantic City Dr. Beebe had had four more cases, making thirteen in all which he had treated by this method, and he thought that it was possible in every instance to state that these patients were somewhat better off when the acid treatment was begun. The amount of acid used varied somewhat with the different cases, but in most of them fifteen minims of the 10 per cent. acid was diluted to one ounce, and from four to twelve ounces of acid of that concentration was given to the patient after each meal, the acid being taken gradually over from one-half to one hour. In three of the cases a trial was made to see whether, after

they had begun to improve under the use of hydrochloric acid, the patient would relapse when the acid was stopped. In these three cases he was able to state positively that when the acid was interrupted the patients changed for the worse; but when the patient had reached a state of improvement so that his blood showed from 50 to 60 per cent. hemoglobulin and histologically a marked improvement, interruption of the acid treatment was not followed by an immediate change for the worse. He believed the treatment to have some physiological basis, but regarded the administration of large quantities of hydrochloric acid as symptomatic treatment only, and its value was as yet undetermined, but from the results obtained in these thirteen cases it would seem to be an advisable procedure to use.

The Therapeutic Significance of Pilocarpine Glycosuria in Sugar-Free Diabetes.—Dr. Rudisch said that in introducing atropine salts in the treatment of diabetes he had assumed, as a working hypothesis, that in the majority of the cases of so-called pure or neurogenous sugar excretion this was not due to a diminution, but to an increase in pancreatic secretion as the result of nervous influences. It was possible at this time to enumerate the grounds on which this deduction was based. Instances of hypersecretion in other secretory organs in conditions of nerve hyperexcitability were commonly met with in the form of polyuria, diarrhea, hyperchlorhydria, etc. In this hypersecretion atropine was designed to counteract. The results had fully justified his expectations, and it remained to be seen whether an antagonist of atropine, *i.e.* a drug known to produce hypersecretion in the pancreas, would produce opposite effects and thus verify his assumption. In the cases in which pilocarpine was first tried the results were quite inconstant. These earlier failures might be explained as follows: The drug was administered to patients with sugar-free urine who were on so strict a protein diet that the increase in pancreatic secretion following the administration of the pilocarpine was insufficient to cause sugar excretion. For his later experiments Dr. Rudisch selected patients who were on a diet representing the limit of their carbohydrate tolerance. The histories of these cases, apart from the sugar excretion, contained no points of interest. The first patient, forty-eight years old, excreted small amounts of sugar from the date of admission, November 27, when the urine became sugar-free and remained so for one week. She then received one ounce of bread, and this was followed by a prompt reappearance of sugar in the urine; the sugar again disappeared when a strict protein diet was given. After two weeks, during which time the urine remained free from sugar, two doses of pilocarpine, one-sixth of a grain each, were given during twenty-four hours, with one similar dose on the following day. As was to be expected, since the patient was on a strict protein diet, no sugar appeared in the urine during the next few days. One ounce of bread daily was now added to the diet, and the urine was carefully observed over a period of a week, during which time no sugar could be detected in any of the specimens examined. At the end of this time, January 4, pilocarpine, one-sixth of a grain, was given by mouth at 8 A.M., and the urine examined at intervals of two hours throughout the day. At 10 A. M. one-quarter per cent. of sugar was found to be present, the quantity gradually diminishing through the day. On the following day the experiment was repeated with practically the same results, making a detailed account superfluous. For eleven days small amounts of sugar continued to be present in the urine. Attempts to suppress the sugar excretion through atropine were interrupted on account of the unusual susceptibility of the patient to this drug. For the past four days the urine had again been sugar-free. The second case was that of a woman who was admitted on December 16, 1909, with 2.8 of sugar; under a strict protein diet and atropia, the urine became sugar-free within three days. On January 1 milk was added to her diet without resulting in the appearance of sugar in the urine. On January 5, pilocarpine, one-sixth of a grain, was given by mouth. During the following ten days the urine constantly showed more or less marked traces of sugar, at one time reaching 1.2 per cent., the reaction with Fehling's solution finally disappearing on the evening of January 15. Atropine, grain one-sixtieth, was ordered on the fourth day after the pilocarpine was given, and was continued for three days. For the last four days a large dose of sodium bicarbonate was administered every hour, a drug that was known to inhibit secretion also. It was of interest to note that the glycosuria following the pilocarpine, though not intense, was quite obstinate, persisting for ten days in each of the above cases. This was in accord with the common clinical experience that a single dietary indiscretion was often followed by glycosuria lasting over a week or more. And so opium, sodium bicarbonate, and atropine diminished pancreatic secretion; whereas pilocarpine and amylacaceæ increased pancreatic secretion, and consequently sugar production. Dr. Rudisch thought they were entitled to say that the treatment of neurogenous diabetes was put on a physiological basis and was no longer a matter of empiricism.

Dr. Graham Lusk said that Dr. Rudisch came to the laboratory of the Cornell University Medical College last winter and spoke of administering atropine and pilocarpine to dogs with phlorizin diabetes. Dr. Ringer had made this investigation and found that both atropine and pilocarpine were without influence on the nitrogen elimination in phlorizinized dogs. Of course, this simply showed that these drugs had no influence either upon the excretion of sugar through the kidney, or upon the sugar production in the body. Whether these drugs had an influence upon the pancreas, as stated by Dr. Rudisch, was another matter. It might be that atropine, which acted to diminish the secretion of pancreatic juice, might act to conserve the internal secretion of the gland; whereas pilocarpine, which, on the other hand, produced an increase in the secretion of pancreatic juice, might thereby act to diminish the activity of the internal secretion.

A Case of Myelogenous Leukemia with Diabetes.—Dr. Alfred Meyer reported this case. The patient was a woman, forty-eight years old, who was at the menopause. She did not appear to be particularly sick, although she had been ill with diabetes for four years. She weighed 155 pounds, and did not seem to be anemic. The symptomatology of diabetes was very plain, but the other condition, myelogenous leukemia, had not been recognized before her admission to the hospital. When she was first examined at the hospital there was noted a large splenic tumor. The liver was enlarged and easily palpable. The urine contained from 1 to 2 per cent. sugar, the highest daily excretion being 44 grams. The blood count showed 75 per cent. hemoglobin, about 240,000 leucocytes, 50 per cent. polymorphonuclears, and 40 per cent. large and small lymphocytes; there were from 9 to 12 per cent. myelocytes, and the erythrocytes numbered about 4,250,000. There was tenderness over the sternum. One small hematoma was found, and some ecchymotic spots over the body. Retinal hemorrhages were found in the eye. This patient died one month after admission. Within one week of her death she was seized with hemorrhages from the bowel. She then began to run a septic temperature curve, ranging as high as 106°. Dr. Meyer called attention to the work of Dr. Cabot and his careful study of leukemia which was published in Dr. Osler's book; he there stated that in his experience with sixty or seventy cases hemorrhage was a very common symptom in four-fifths of them, but that a fatal hemorrhage from the bowel in myelogenous leukemia was rare, and that even the bleeding did not appear to come from any large blood vessels, but was a general oozing. What was of particular interest in the report of this case was the

relationship between the two diseases in point of time. One observer had reported three cases, two quoted from the literature and one observed by himself, in all of which the diabetes appeared first and the myelogenous leukemia later. In Dr. Meyer's case the diabetes probably antedated the leukemia, because he had evidence that the diabetes had been discovered four years previous, and very likely exceeded that period; it was exceptional for even a myelogenous leukemia to last four years. With regard to the etiology, there did not appear to be any relationship between the development of the leukemia and the diabetes; the frequency of diabetes and the variety of the complication was alone sufficient to discountenance such a view. Dr. Meyer then referred to the occasional difficulty in differentiating splenic tumors from left renal and retroperitoneal tumors, and, although this did not apply in his case, he had inflated the colon from the rectum in order to test the correctness of the view. If the tumor was a splenic one, no effect would be noticed, as proven by the case he reported; whereas if it was a renal tumor, or one starting from the retroperitoneal space, the colon could be percussed in front of the tumor. The patient died four weeks after admission, and the postmortem revealed small hepatic abscesses, in addition to the other expected lesions. Dr. Cabot reported that three times in his experience cases of myelogenous leukemia had been mistaken for hepatic abscesses. Dr. Meyer wondered whether it was not possible that these were cases of leukemia complicated with hepatic abscesses. As to the treatment, sixteen or seventeen years ago he said that he had a patient with myelogenous leukemia, and used hypodermically freshly prepared carbolic glycerine extract of thyroid gland. The leucocytes were one in three; there were many large hematomata, and hemorrhages from the nose, rectum, and uterus. His colleagues were astounded at the marvelous improvement which followed this plan of treatment, plus inhalations of nascent ozone and the rectal injections of artificial serum. However, the patient went to Tennessee, where she subsequently died. Dr. Meyer did not know whether it was the thyroid, the carbolic acid, or the glycerine that caused an improvement in her condition Dr. Meyer said that in at least one or two cases of leukemia that had been under his charge, the *x*-ray had been used with marvelous results in reducing the size of the spleen, but at the same time the patient's downward course appeared accelerated. He did not look upon the spleen as being the primary source of the trouble. He thought that possibly the rapid reduction in the size of the spleen caused the absorption of the products of decomposition, and injured the patient. The condition might be a species of toxemia. The *x*-ray, if at all used, might more safely be used in small doses and at long intervals. The extra precaution would be additionally justified when there was a coexisting diabetes.

A Case of Melanosarcoma.—Dr. Henry W. Berg reported this case. The patient was a woman, thirty-two years old, and married; she had had four living children; three children had died and she had had one miscarriage. Up to about four years ago she had been perfectly healthy, when a pigmented mole appeared on her back near the left scapular angle, which took on an extraordinarily growing activity. It projected from the skin and began to ulcerate; her family physician removed it. Six months after the operation she began to have pain in her abdomen; she vomited frequently and had dizzy spells. She then noticed the appearance of enlarged glands in the neck and axilla; also small elevated spots, the size of millet seeds. In July of this year she complained of pain in the scar where the original pigmented mole had been. On examination the skin showed the following: Scattered over the chest, back, and extremities were numerous tumors, varying in size up to three millimeters. Some of them were merely pigmented spots; others were distinctly elevated a millimeter above the surface. They were smooth, glistening, and brownish-black in color. There were several such lesions on the lower jaw and two on the dorsum of the left foot. Just inside the left scapula was a scar; at the upper end was a flat, black, rough circular tumor the size of a watermelon pit. Over the right iliac region there was a pedunculated, hard, brownish tumor, slightly ulcerated. There was a similar tumor within the left axilla. There were a few small inguinal glands; no epitrochlear glands were found to be enlarged. The posterior cervical glands on the right side, however, were markedly enlarged, hard, somewhat matted together, but not tender. There was a somewhat small, black, soft, somewhat movable tumor growing from the gum of the left side of the mouth. The liver, somewhat rough and nodular, projected two fingers below the free border of the ribs. Projecting from the lower border was a mass in the region of the gall-bladder which was the size of a large egg, and which could be traced as attached to the liver. The spleen was felt two fingers below the free border of the ribs, and was firm and rough. In the abdominal wall, three fingers above and inside the anterior superior spine on the left side, was a distinct nodule, not tender, hard, or movable, and about the size of a hazelnut. There was an occasional rise of temperature. The blood showed no abnormality except an anemia, and this, together with the enlarged glands in the neck and axilla, led one to think of Hodgkin's disease. It was not until a month or so ago that an exquisite skin lesion appeared, and immediately a diagnosis of melanosarcoma was made. The primary lesion was in the pigmented mole; the metastases in the abdomen, glands in the neck and axillæ were extremely interesting. A portion of one of the growths was excised, and the pathologist reported that it was a melanosarcoma or carcinoma. The urine showed the melanin pigment. The patient was very anemic, and had occasional rises in temperature. At first she was treated with arsenic injections. She was now receiving Coley's fluid.

A Case of Acromegaly with Mediastinal Tumor.—Dr. Morris Manges reported this case. The patient was a laborer, forty-five years old, admitted to Mt. Sinai Hospital November 25, 1909. He entered the hospital because of hemoptysis, cough, and a profuse expectoration. The acromegaly began at the age of 15 years and gradually increased. Two months prior to admission he began to have a cough, a mucopurulent expectoration, and pain in the upper right chest, particularly on deep inspiration. There was slight dyspnea on exertion. The sputum had a very foul odor. About one week after the onset of his trouble he had difficulty in swallowing. The pain in the chest became more and more severe. He had lost twenty pounds in weight. The patient was a very large, muscular man, although very emaciated. The facial appearance was that of acromegaly. He coughed and expectorated a bloody sputum. His voice was somewhat hoarse. There were numerous large and small glands in the left axilla. There was marked asymmetry of the chest, with marked bulging of the lower right quadrant. About one hand's breadth below the left nipple was noted a small, soft subcutaneous mass, freely movable over the deeper tissues. At the angle of the right scapula was another soft mass, the size of a fist and freely movable. A similar mass was found lower down. Just inside the spine of the right scapula another mass was found. There was no tenderness over any of these lipomatous tumors. There was marked board-like flatness over the upper right lobe of the lung, extending down to the second rib. There was an emphysematous note over the left apex. The breathing was rough over the entire right apex. The voice signs were diminished. No râles were heard anteriorly. There was marked dullness in both interscapular regions. Numerous fine dry râles were heard at the base of the right axilla. There

was a marked arteriosclerosis of the vessels. The liver extended to two fingers below the free border of the ribs. The hands and feet were very large. The great toe was especially large. There was no thyroid gland. Sugar was absent, and none was found even after giving 100 grams of sugar. On November 28 a rough, diastolic murmur was heard over the pulmonic orifice which was transmitted toward the apex. On December 1 there was a slight adductor paralysis of the larynx. The *x*-ray plate showed a large mass in the upper part of the chest, most of it being on the right side. Its maximum breadth was at the seventh rib, where it measured about seven inches. On December 6 marked dysphagia was noted and a stomach tube could be passed twelve and a half inches from the teeth. On December 11 there was a very severe dyspnea, laryngeal spasm, and bilateral adductor paralysis. The patient was unable to cough or swallow. He suddenly had a sensation of choking and expired. No tubercle bacilli were found in the sputum, and the v. Pirquet test was negative. The white blood cells numbered 7,500 and the hemoglobin was 85 per cent. The differential count showed polymorphonuclears to be 76 per cent., the large lymphocytes 6 per cent., and the small lymphocytes 18 per cent. At autopsy the skull could not be examined. No thymus gland was found. The esophagus showed no abnormalities, but it might have been compressed. At both apices were found old adhesions. There was no fluid in the chest. There was found a large posterior mediastinal tumor, 13 cm. in diameter, adherent to the right lung above the hilus; this tumor compressed the azygos vein and the right vagus nerve and left recurrent laryngeal nerve. The right innominate vein passed through the middle of the tumor and could be followed to a point where it was occluded. There was a complete concretio pericardii. Both ventricles were hypertrophied. The right ventricle was markedly infiltrated with fat. The muscle was brown in color. The trabeculæ of the left ventricle were flattened. There were no abnormalities of the valves. The liver weighed over five pounds. It was markedly congested and at the periphery there was fatty degeneration. There was an hyperplasia of the lymphatic apparatus of the spleen. The kidneys showed no chronic lesion. The diagnosis made was mediastinal tumor and polymorphocellular sarcoma (lymphosarcoma).

Recurrent Laryngeal Paralysis Due to Hypertrophied Heart.—Dr. Morris Manges reported the case of a boy, fifteen years old, who, during the past two years, had had repeated attacks of failing compensation. The examination revealed an enlarged heart, with the apex in the posterior axillary line and the sixth interspace. It was a huge heart. There was pulsation in the episternal notch. There was a double aortic murmur, a mitral regurgitant murmur, a Corrigan pulse, and an accentuated second pulmonic sound. There were no signs of a pericarditis. There was a large and pulsating liver. There was a left recurrent laryngeal nerve palsy due to compression of the nerve between the aorta and the dilated left auricle. This case showed how such a condition might simulate an aneurysm, especially when there was pulsation at the second and third left spaces, as there was in this case. Dr. Osler had reported three cases in which he stated that the compression might also occur between the dilated pulmonic veins or the left pulmonary artery and the dilated left auricle. Osler's three cases were of double mitral disease, two with autopsy, where the nerve was found to be compressed between the left auricle and the aorta. The condition was first described by Ortner; in his case aneurysm had been suspected, but the autopsy showed the compression of the left recurrent laryngeal nerve between the aorta and the enlarged left auricle. Dr. Manges exhibited an *x*-ray plate showing an enormous enlargement of the heart, especially the left heart. The aorta was not enlarged.

Dr. Forbes R. McCreery reported the case of a servant girl with paralysis of the left recurrent laryngeal nerve; there was a complete paralysis of both the true and false cords. She had a hypertrophied heart, arteriosclerosis, and the arterial tension was about 170. There were no evidences of aneurysm. He could not find anything to account for this paralysis except the hypertrophied condition of the heart. There developed later edema of the feet and she became very much emaciated. At the present time her condition was practically the same, except that under treatment the edema had disappeared and her general condition had somewhat improved. The condition in the larynx remained the same. The only explanation he could give was that the greatly hypertrophied heart pressed upon the recurrent laryngeal nerve and so caused the paralysis.

A Case of Typhoid Fever, with Multiple Thromboses, and Infarcts of the Lung, and Embolism of Pulmonary Artery.—Dr. Morris Manges reported this case. This was a very long protracted case and showed the value of hospital care, careful stimulation, and proper feeding. Infarctions occurred in the left apex on the forty-ninth day of the typhoid and in the right lung on the fifty-fifth day. Embolism of pulmonary artery occurred. The left external jugular became thrombosed and later the right. Many small hemoptyses occurred with the infarctions and the patient suffered from bed sores. There was edema of the left upper extremity. Phlebitis of the upper extremity was very rare, Curschman reporting only two cases in the axillary and subclavian veins. Keen found it in only four cases of 128 cases of thrombosis in typhoid fever. In the case reported there was absolutely nothing noted in the veins of the lower extremities. Dr. Whiting had examined this patient to discover if there was any possible relationship between sinus thrombosis and the jugular thrombosis. With regard to the source of the emboli, they did not come from the intestinal lesions; they probably came from the thrombosed veins, or possibly from thrombi in the right heart. There were no ill effects from the infarcts, although cases had been reported where they had led to gangrene. Dr. Manges thought that in this case the lung infarcts were the result of the thromboses. Embolism of the pulmonary artery was usually a fatal condition. The symptoms in this case resembled those in Eichhorst's case. A recovery followed a very long and tedious illness of 130 days.

Qualitative Test for B-Oxybutyric Acid in the Urine.—Dr. Julius Rudisch, working upon Black's basic idea of the demonstration of β-oxybutyric acid through its oxidation into diacetic acid, had devised methods which he wished to present. Ten to 15 c.c. of urine, which should be acid or, if necessary, slightly acidified with very weak acetic acid, were brought to the boiling point, and a small quantity of lead peroxide added to the hot solution, after which the mixture was again brought to the boiling point. It was then allowed to cool for ten to twenty minutes. A small portion was then filtered into a test tube containing dilute liquor ferri chloridi. The latter he made by adding five to ten drops of the iron solution to three to five c.c. of a saturated salt solution. In the presence of β-oxybutyric acid a red ring formed at the junction of the two fluids. Dr. Rudisch had obtained equally good results by adding about two c.c. of Fehling's solution of copper to the boiling urine, together with a small quantity of zinc dust, and proceedings as with the peroxide of lead. The following precautions should be observed in carrying out the above tests: (1) If diacetic acid was present in the urine, it should first be removed by boiling. (2) Salicylates invalidated the test, as in themselves they gave a violet color on the addition of iron. (3) An excess of acetic acid should be avoided, as this would also give a red ring due to the formation of acetate of iron. The latter would de-

compose on boiling, yielding a precipitate of basic iron acetate.

Pseudotyphoid Fever; a Clinical Study.—Dr. Nathan E. Brill read this paper. What he termed "pseudotyphoid fever," which name was only tentative, was an acute infectious disease of unknown origin and unknown pathology. It was characterized by a short incubation period of four or five days, then a period of continuous fever accompanied by an intense headache, more or less apathy and prostration, a profuse and extensive maculopapular eruption, all of about two weeks' duration; then the temperature would abruptly fall, either by crisis in a few hours, or by a rapid lysis within two days, and the symptoms then would all disappear. The total number of cases that he had records of was 221. His paper was based, however, on the last 50 cases seen in the wards of Mt. Sinai Hospital. There were 34 males and 16 females. There were 30 Russians, 12 Austrians, two each of this country and of Ireland, one German, and three whose nationality was not noted. The month of appearance of this disease showed the following: January, 1; February, 3; March, 3; April, 10; May, 3; June, 8; July, 8; August, 2; September, 6; October, 11; November, 3; December, 2. The disease was most commonly met with between the ages of 20 and 40, 33 being seen during this period. Between the ages of 10 and 20 there were 9 cases; between the ages of 20 and 30, 19 cases; between the ages of 30 and 40, 14 cases; between the ages of 40 and 50, 4 cases; between the ages of 50 and 60, 2 cases; between the ages of 60 and 70, 2 cases. The youngest patient was 17 years old and the oldest 65 years old. The incubation period varied in duration from a sudden onset, without prodromal symptoms, to fourteen days. During this time the patient suffered from headache, general malaise, anorexia, and constipation. The average duration of the incubation period in this series of 50 cases was 4.8 days. In 15 cases it could not be ascertained; in 35 it varied from a few hours to 14 days. The onset might be gradual or sudden, and was accompanied by a chill, or chilly sensations, nausea, vomiting, and severe headache; occasionally there were general body pains. In 19 cases the onset was sudden; in 31, gradual. Epistaxis was uncommon, being noted but three times in this series of cases. Among the symptoms noted, headache was invariably present and was of an agonizing character, more severe than in typhoid fever, and dispapeared with the fall in the temperature. Apathy was marked in the majority of the cases. In six cases it was extreme, in 17 it was marked, in 12 it was absent, and in 15 it was not noted. In the cases with rigidity of the neck spinal puncture was done and an examination of the fluid cytologically and bacteriologically showed no evidences of a meningitis and no organism was isolated from the cerebrospinal fluid. The pulse in these cases was rather slow and did not rise markedly with the temperature elevations. It was full, soft, and of low tension. The temperature, as a rule, began to rise between the third and fourth day of the disease. It reached its height in two or three days and average between 103.6° and 104.2°; it was slightly higher in the evenings, the remissions between morning and evening not varying more than one to one and a half degrees. With the exception of these remissions, the temperature was uniform. Until the day before the beginning fall, a precritical rise was noted in four cases to over 105°; the precritical rise, however, was not the rule. On the twelfth to the fourteenth day, the temperature began to fall. The fall was quick and abrupt and, in some of the cases, within ten hours from over 105° to normal. The fall by crisis was observed in 16 cases, rapid lysis (thirty-six hours) in 17, and in 17 the decline occurred within sixty hours. The conjunctivæ were suffused and congested in 28; not affected in 18; not noted in four. The face showed an expression of pain; the skin of the forehead was wrinkled and the brows were contracted. Any attempts at moving the patient induced a more marked expression of pain which was referred to the head. The tongue was coated; it was usually moist, only occasionally being dry and furred. The eruption was petechial in three cases. The date of its appearance could not be definitely stated, but it appeared about the sixth day. Herpes labialis was noted in four cases of this series. Constipation was a marked feature, being present in 42 cases; in six the bowels were regular and in two the diarrhea followed a previous constipation. Tympanites was not a feature of the disease. A slight distention of the abdomen was noted in nine patients. The sensorium was dulled; the patients resented being disturbed and were quite irritable. The spleen was not infrequently enlarged so as to be palpable. It was distinctly felt below the costal margin in 17 cases of this series. The average white blood count was higher than in typhoid fever. There was no tendency to leukopenia, the average count being between 8,000 and 11,000; when bronchopneumonia existed as a complication, the count was much higher; in one case it was 23,600. Taking the average of the series, only one of which no count was taken, the count was 9,394, the lowest being 4,200. The polymorphonuclears were about 70 per cent. and the lymphocytes 30 per cent. as the average in their series. A faint trace of albumin was noted in many of the cases. The diazo reaction was present in nine cases, absent in 30, and was not noted in 11 cases. Among the complications bronchitis was the most common, occurring in 24 of this series. Bronchopneumonia was noted occasionally, but was only present in four of the cases. The disease lasted about two weeks. In their series of cases the average duration was 133 days. In one case it lasted but five days and in another 22 days, these being the minimum and maximum limits. Ten of these patients had had typhoid fever previously; 37 had not had typhoid previously; three could not give any data as to a previous typhoid. Agglutination with the typhoid bacillus reaction was absent in all of the 221 cases. The test was made daily in almost all of the cases up to the time of their discharge from the hospital. In only the last 19 of the series was the daily test discontinued owing to the fact that a positive reaction had never been found. In the last 19 patients the test was made every third day. Agglutination tests of the patients' serum were made against the paratyphoid and intermediate para-colon group, including all the available group strains that the Mt. Sinai Hospital laboratory could obtain. No positive reaction in any of these had ever been obtained. These reactions were made in a large number of the cases, the details of which the laboratory could report. Blood cultures were made in most of the cases, averaging two cultures in the number, *i.e.* in some patients only one was taken and in others as many as four. No organism had ever been discovered or isolated in any of these. The blood obtained from puncture of the spleen in a number of these patients likewise proved culturally negative. Feces and urine were examined culturally and from neither could an organism be obtained which could be regarded as the causative factor in this disease. Many of the spots were subjected to cultural and microscopical examination with negative results. There had not been one fatality among all these patients. No relapse from the disease had ever occurred. Dr. Brill insisted that this disease was a distinct clinical entity and was entitled to a definite place in medical nosology. It had absolutely no relationship to typhoid fever, from which it was distinguished in every clinical feature, particularly in the temperature curve, in the eruption, the absence of the Widal reaction, and the total lack of evidence from blood cultures. The eruption was wider spread, covering the trunk and extremities even to the palms and soles in some of the cases. The spots were irregular in outline, not circumscribed or lenticular and did not, as a

rule, disappear on pressure; they were larger and not as high as the typhoid fever spot and dull red in color. The eruption was more like the typhus fever eruption than the typhoid, and, in his opinion, was one of the characteristic features of the disease under discussion. The disease was apparently not communicable; no case had ever developed in the general wards where these cases were, in which respect it was entirely unlike typhus fever.

Dr. Warren Coleman said that Dr. Brill's paper was too important to be passed over with the usual polite encomiums. If Dr. Brill had discovered a new disease, full credit should be given to him; if, on the contrary, he had failed to eliminate other possible diagnoses, this fact should also be made known. Here was a disease which was so like typhoid fever that Dr. Brill had called it "pseudo-typhoid." In his opinion it lacked no essential symptom of mild typhoid fever. The patients suffered from headache, fever, an increasing malaise, which ultimately drove them to bed; there was also enlargement of the spleen; sometimes there was a dicrotic pulse, constipation, and an eruption. The cases were usually of short duration and some had ended by crisis. Dr. Brill believed that the eruption was characteristic, and that it was not like the typhoid eruption. He had been kind enough to invite him to see within the last few days two cases in the Mt. Sinai Hospital. Defervescence had occurred in one case and, though he found a few spots on this patient, it would not be fair to draw conclusions from them. The other case was acutely ill. She had an extensive eruption over the back, chest, arms, and thighs, but as Dr. Brill thought the rash was not typical, no opinion would be expressed about it. The impression Dr. Coleman received from these cases was that they were like mild typhoid fever. He said that in Bellevue Hospital he had proved cases, which appeared to be similar, to be cases of mild typhoid fever. Dr. Brill was also kind enough to show some case-histories and these too resembled the typhoid cases he had seen at his service at Bellevue Hospital. The fact that in none of Dr. Brill's cases were positive bacteriological examinations of the blood, or positive serum reactions obtained, demanded consideration. No one who was familiar with the work of the pathological department of Mt. Sinai Hospital questioned for an instant the results of the examinations made there. It was the interpretation of the results which Dr. Coleman believed to be at fault. A single or even several negative bacteriological examinations of the blood in a given case did not prove that the patient was not suffering from typhoid fever. Dr. Buxton and he had failed to discover the typhoid bacillus in typical cases of typhoid fever until the third or even the fourth examination, the same method being employed each time. There were so few data concerning the results of the bacteriological examinations of the blood in cases of mild typhoid fever that it would be unwise to attempt to draw conclusions. They simply did not know how often they might expect to recover the bacillus. Before taking up the discussion of the serum reactions, he said he wished to state that he included in the term typhoid fever all typhoid-like cases of infection by whatever member of the typhoid-colon group of bacilli they might be caused. In the majority of Dr. Brill's cases, the serum had been tested against the typhoid bacillus only; likewise in the majority of cases, serum tests had not been made daily. If the results which Dr. Hastings and he had obtained might be depended upon, these examinations were not sufficient for diagnostic purposes. They found that a positive reaction might be present for only a day or two in mild typhoids and, therefore, daily examinations were required to prove a negative. Furthermore, to exclude infections by other members of the typhoid-colon group, daily examinations must be made. Dr. Coleman did not believe that Dr. Brill had proved that he had found a new disease.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of February 26, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	731	167
Diphtheria	391	44
Measles	1,246	22
Scarlet Fever	655	40
Smallpox	—	—
Varicella	201	—
Typhoid Fever	34	7
Whooping Cough	22	3
Cerebrospinal Meningitis	3	3
Malarial Fever	—	—
Totals	3,283	286

The Wassermann Reaction in Leprosy.—Alberto Serra gives the results of his experiments on the Wassermann reaction, as applied to leprosy. He made the tests in seventen lepers, eight of mixed type, six of tubercular leprosy, and three of leprosy of the nerves. The test was positive in all cases except in nerve leprosy pure and simple. He believes that the serum of lepers has a marked affinity for the extract of the lepromas, which speaks for the specific nature of the test. The completeness of the test varies with the greater or less florid condition of the disease. As the disease declines in acuteness, as in syphilis of the nerves and late tubercular leprosy, the test is less evident.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 25, 1910:

TUBERCULOSIS OF THE KIDNEY WITH REPORT OF CASES.*

BY HENRY H. MORTON, M.D.,

BROOKLYN, N. Y.

CLINICAL PROFESSOR OF GENITOURINARY DISEASES IN THE LONG ISLAND COLLEGE HOSPITAL, GENITOURINARY SURGEON TO THE LONG ISLAND COLLEGE AND KINGS COUNTY HOSPITALS AND THE POLHEMUS MEMORIAL CLINIC.

TUBERCULOSIS of the kidneys is a disease of young persons occurring almost always between the ages of twenty and thirty. In point of frequency men and women are similarly affected. In the great majority of cases the tuberculosis is apparently a primary infection of one kidney, and it is not possible to demonstrate active foci of tuberculosis in the body, although they may exist latent and unsuspected. This is a most important clinical fact, for upon it is based the modern treatment of tuberculosis of the kidney, for an early nephrectomy removes the tangible focus of tuberculosis from the body. After the kidney is removed, further development of the infection does not occur, and the patient's life is saved.

The kidney may be infected in two ways, either from a focus of tuberculosis, from which the bacilli are carried through the blood in the form of emboli and deposited in the capillaries of the kidney, or the bacilli are taken into the blood through the stomach or lungs and are carried to the kidney, developing foci of tuberculosis at the point of weakened resistance. This is the so-called hematogenous infection and is by far the most common mode. One kidney alone is attacked at first, and after several months the other becomes infected. This is shown by postmortem examinations, which demonstrate that after long standing tuberculous disease, both kidneys are affected. The fact that in the early months only one kidney is infected is proven by catheterizing the ureters and examining the urine from the right and left sides. The necessity of early diagnosis is an important suggestion for treatment, for if the diseased kidney is promptly removed before infection of the other one, nephrectomy prevents further trouble and is a life-saving operation.

This applies only to those cases of what might properly be called primary tuberculosis of the kidney, in which foci cannot be demonstrated elsewhere in the body.

In a few cases the tuberculosis apparently begins in the prostate or epididymis and both kidneys are affected secondarily by an extension of the process, either by metastasis through the lymph vessels and periureteral tissues, through the blood current, or by a direct ascent of the bacilli through the ureters to the pelvis of the kidney. The extension of the process is slow, and the kidneys are only attacked shortly before the death of the patient, which occurs from ulcerative perforation of the bladder and urethra into the rectum.

It was formerly supposed that the kidneys were usually infected by a direct ascent of the tubercle bacilli from the bladder through the ureters, and while this is the mode of infection in pyelitis, occasioned by stagnating urine in a bladder which cannot empty itself, as a result of stone, stricture, or enlarged prostate, it is known to-day that an ascending infection of the kidneys is a rare event in tuberculosis. An exception to this general rule takes place when the tuberculous process begins in the vas deferens or seminal vesicles. In these cases the process extends to the ureter, causing a stricture with stagnating urine. At night, with the patient in a recumbent position, the bacilli readily make their way through the ureter into the pelvis of the kidney and cause pyelitis.

The pathological anatomy of tuberculosis of the kidney consists in the deposit of isolated foci of tuberculosis in its parenchyma, which become cheesy, break down, and the pus is discharged into the pelvis of the kidney. After a time the foci coalesce and form large cavities, often communicating and filled with pus; or large abscesses may form at one pole and a good deal of the secreting parenchyma remains. Finally, if the patient lives long enough, the parenchyma is entirely destroyed and the kidney is converted into a mere shell, surrounded by a thickened capsule and containing cyst-like cavities filled with cheesy pus. The ureter sometimes becomes occluded and the pus has no exit, or the ureter remains patulous and the kidney becomes converted into a small hard mass of fibrous connective tissue. Interstitial nephritis always ensues after a time and is caused either by the tubercle bacilli themselves or their toxins. Perinephritic abscess often follows as a complication and is formed by an ulceration from the tuberculous deposit extending through the parenchyma and perforating into the fatty capsule of the kidney. The pus is discharged through the sinus thus formed and retained within the fatty capsule. Where one kidney is the seat of a tuberculous deposit, the second kidney remains healthy for a time, but ultimately becomes infected through the blood. The fatty capsule of the diseased kidney becomes very much thickened and is converted into dense fibrous connective tissue, closely adherent to the kidney. This adds greatly to the difficulty of nephrectomy, so that subcapsular enucleation of the kidney may have to be performed in order to remove it.

The symptoms of tuberculous kidney are slight at first; a little impairment of the appetite is noted, with perhaps some feverishness at night. Later, loss of weight is noticeable, and there is an evening rise of temperature of 101° to 102°. If pyone-

*Read before Kings County Medical Society, November 16, 1909.

phrosis or perinephritic abscesses develop, marked septic symptoms follow. If nephritis becomes marked, symptoms of uremia occur; and if the ureter becomes occluded, pains in the loin radiating along the course of the ureter resembling renal colic. The symptoms are not constant, but remissions, with

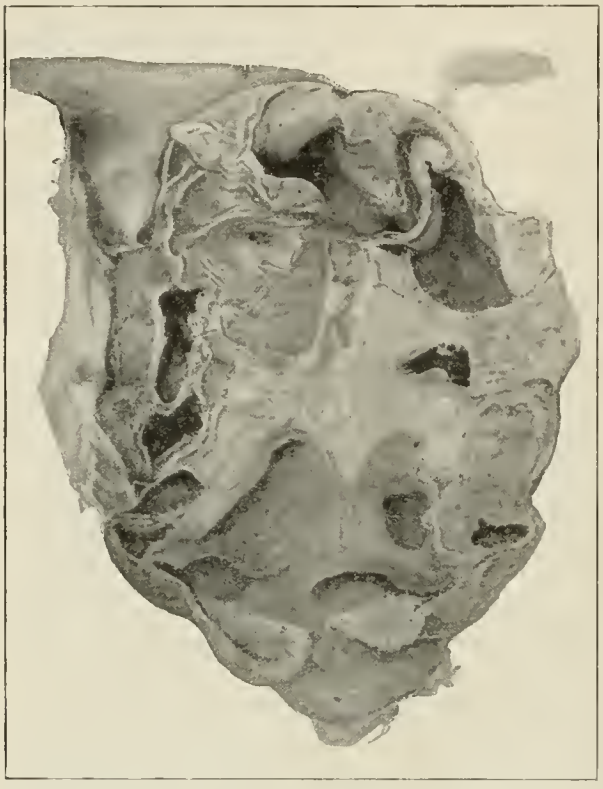

Fig. 1.—Case 3. J. L. M. Tuberculosis of the kidney; isolated foci have broken down and formed cavities, filled with pus, several of which communicate.

repeated occurrences, are rather characteristic of the disease. In the early stages, frequency of urination, particularly at night, is observed; but later, when the bladder has become involved with the formation of typical tuberculous ulcers, urination may occur every ten to fifteen minutes. The pain and tenesmus are intense, the urine is foul, containing quantities of pus and more or less blood. The urinary examination shows pus in the urine, unless the focus of tuberculosis does not communicate with the pelvis of the kidney, in which case there is none. When the abscesses break they discharge into the pelvis of the kidney, and pus again appears in the urine. In the early stages a moderate amount of pus is observed in the urine, which is remittent in character, but later large quantities are poured forth. Hematuria may occur, but not necessarily. A free hematuria usually denotes ulcerations at the apices of the pyramids. The urinary examination shows, in addition to the pus cells, polyuria of low specific gravity and acid reaction. Albumin in slight quantities is present and accounted for by pus or blood. If nephritis occurs, considerable quantities of albumin are found, together with granular and hyaline casts. The tubercle bacilli are often difficult to find. Many slides may be examined and none discovered. Pain is not a marked feature of tuberculosis of the kidney, unless the ureter is blocked, preventing the urine from flowing out and damming it back on the kidney. Tumor is difficult to feel, as the kidney is not much enlarged unless pyonephrosis or perinephritic abscess develops. If this occurs, a tumor of considerable size may be easily palpated

In making the diagnosis, the practitioner should suspect tuberculosis of the kidney in every case of cystitis, especially in young persons, which is not due to stone or stricture and which does not clear up under bladder washing. Another point which should increase the suspicion of tuberculosis is the fact that a tuberculous cystitis is always made worse by bladder washing with nitrate of silver solution. The failure to fine the tubercle bacilli on examining the urine from the bladder does not exclude tuberculosis of the kidney. If the bacillus is found, it is positive evidence of the presence of the tuberculosis; but it is like the proverbial needle in the haystack and many slides may be examined without discovering one. If the microscopic examination of the urine in a case of cystitis or pyelitis shows pus cells alone, without the presence of microorganisms of any kind, the absence of any bacteria is strongly indicative that the inflammation is tuberculous in origin. If the tubercle bacilli are found, however, it is a positive evidence and the diagnosis is established. Care should be taken not to mistake the smegma bacillus for the bacillus of Koch, which it closely resembles.

A valuable method of determining the presence of tuberculosis in the body is an injection of tuberculin: 1 cc of a 1 to 1000 solution in 1/2 per cent. carbolic acid, of old tuberculin Koch, is injected hypodermically. If reaction follows within a few hours, and the temperature goes above 102°, it denotes tuberculosis in the body somewhere. The writer has found this to be invariably the case, except in the presence of active syphilis. When syphilis is present, a rise of temperature above 102° occurs following the injection, even when no tuberculosis is present in the body. A simpler method of applying the tuberculosis test consists in the vaccination of the patient with old tuberculin, full strength (von Pirquet's test), or the use of an

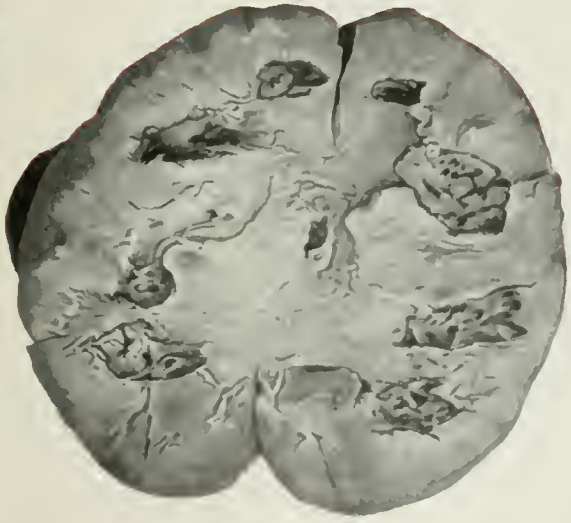
Fig. 2.—Case 5. E. C. D. Tuberculosis of the kidney; the ureter is occluded, the secreting parenchyma of the kidney is destroyed, and the kidney is converted into a mere shell filled with thin pus.

inunction of 50 per cent. tuberculin ointment (Morris test). The writer has made use of these tests a few times and coincides with the general feeling of those who have had larger experience with them, that they are as reliable, easier of application and lack the severe constitutional disturbance when positive, as compared with the tuberculin injection.

CASE 9

CASE 12

CASE 11



CASE 1

TUBERCULOSIS OF THE KIDNEY—MORTON

CASE 9

A large abcess cavity formed at upper pole of kidney. A good deal of secreting parenchyma remains.

CASE 11

Ulceration extending through wall of kidney and perforating into fatty peri-nephritic capsule.

CASE 12

Entire destruction of parenchyma. Kidney converted into a shell surrounded by thickened capsule and containing cyst-like cavities filled with cheesy pus.

CASE 1

Isolated foci of tuberculosis in parenchyma, which are beginning to break down.

The greatest aid to diagnosis is effected by cystoscopy and catheterization of the ureters. In the early stages the bladder is not affected and catheterization of the ureters is not difficult for the surgeon who has familiarized himself with the technique of this operation. In the latter stages, after the bladder has become involved in the tuberculous process, catheterization is always difficult and sometimes impossible. The bladder is contracted, containing only 2 or 3 ounces of fluid, and the ulcers bleed freely, completely obscuring the view.

It has always been supposed that ulcerations seen with the cystoscope around the mouth of one ureter, denoted an affection of the kidney on the same side, but Rovsing (*Zeitschrift für Urologie* Band 3-Heft, 4, 1909) has tabulated one hundred cases of tuberculous kidney, and shows that there is no uniformity about the localization of the ulceration, the ulcers being often located around the healthy ureter or about both ureters, even though one kidney may be healthy.

The use of the Luys' segregator has been advised in the cases where it is impossible to catheterize both ureters, but unless the bladder is free from ulceration, the findings will be misleading, as the urine from kidneys will be contaminated by the pus formed in the ulceration of the bladder.

In the cases which are difficult to examine, the diagnosis has to be worked out step by step. If we can only succeed in getting the urine from one kidney we should endeavor to do so, to determine if the kidney on the side catheterized is healthy or diseased. A view of the ulceration around one or both ureters, together with a decided reaction following the injection of tuberculin would be sufficient evidence of disease, provided the urine drawn from the bladder showed pus. The presence of tubercle bacilli would be confirmative but not essential for the diagnosis. In the cases where the diagnosis offers no special difficulty, after the ureters have been catheterized, the right and left urines should be examined. The presence of blood in the urine drawn, does not necessarily imply disease on that side, as slight bleeding generally occurs from the traumatism of passing the catheter. The presence of pus in the urine denotes disease of that kidney. A comparison of the urea secreted would show the relative functional capacity of the two kidneys. If the urine from one side shows 10 grains of urea with no pus and no albumen, and the urine from the other side shows 2 grains of urea with more or less pus and albumin, it is evident that one kidney is healthy and the other is diseased. The presence of sugar after the injection of phloridzin also shows the secreting capacity of the kidney. After the injection of 1/10 grain of phloridzin, sugar appears in the urine from fifteen to thirty minutes later. The healthy kidney secretes about 1 per cent. of sugar, the secretion from the diseased kidney is less, depending upon the extent of the disease. Cryoscopy of the right and left urines is very troublesome to carry out and does not throw any more light on the secreting capacity of the kidney than the tests of urea and phloridzin. The cryoscopy of the blood in comparison with the urine is useless on account of the number of conditions which change or modify the relative freezing points of each.

Rovsing found that in one-third of his cases where the bladder was involved, the ureters could not to be catheterized. The writer has been successful in catheterizing the ureters occasionally in difficult cases with the patient under a general anesthetic, where, on account of irritability of the bladder, it was impossible for it to retain enough fluid.

The hypodermic injection of 1 drachm of a 4 per cent. solution of indigo carmine, fifteen minutes before catheterizing, is sometimes helpful in finding the ureters. The indigo carmine stains the urine, and jets of colored urine are seen issuing from the mouths of the ureters, which may then be more easily located. The indigo carmine test is also useful as showing the secreting capacity of the kidney. In a healthy kidney the urine becomes tinged with blue in five minutes, and the excretion reaches its highest point from thirty to forty-five minutes after the injection. A delay in the commencement of the elimination and a diminution in the quantity of dye eliminated are indications of a reduced renal function.

The most reliable of all the diagnostic tests are the animal inoculations. Guinea pigs are inoculated by injecting into the peritoneal cavity a specimen of the urine drawn from the right and left kidney and the mixed bladder urine. After three weeks the guinea pigs are autopsied and the presence or absence of tuberculous infection of the pig is proof positive of the condition in the human being.

The prognosis in tuberculosis of the kidney, if treated expectantly, is bad. Pathologists continually discover old scars of tuberculosis in the lungs, but old tuberculous lesions of the kidney are never discovered postmortem. If the case is left without operation, the kidney condition grows progressively worse, ending in its complete disorganization, together with involvement of the other. The only treatment which should be considered in primary tuberculosis of one kidney is an early operation for its complete removal before the other one has become involved.

The great advancement in the modern treatment of tuberculous kidney is due to Nitze's invention of the cystoscope. In former times it was not possible to determine the functional capacity of the other kidney, and the mortality of nephrectomy was very high. According to the statistics collected by Küster, the mortality of 223 nephrectomies through the loin ranged from 36 to 52 per cent. Since the introduction of modern methods of diagnosis, by which the capacity of the other kidney can be determined, Watson and Cunningham has collected the statistics of 292 cases, with a proportionate mortality of 8.8 per cent. These statistics have been further analyzed by Watson and Cunningham, showing as follows: 54 per cent. of patients were cured; 19 per cent. died after convalescing, half from the disease, the others from other maladies; 36 per cent. showed great improvement, but not a cure.

In the presence of tuberculous lungs, a nephrectomy is only contraindicated when the destructive process in the lungs has so far advanced that it is evident that a subsequent healing of the lungs cannot take place. In the presence of a tuberculous bladder, clinical experience shows that a beginning bladder tuberculosis heals speedily after extirpation of the diseased kidney, and tuberculosis of the testicle and prostate are also frequently followed by healing, after the diseased kidney has been removed. If both kidneys have become infected, it is

evidently too late for anything but palliative treatment. In cases in which the development of pyonephrosis and sepsis threaten the patient's death, life may be prolonged by a simple nephrotomy, emptying and draining the collection of pus in the kidney, which must be left in to carry on its necessary function.

Case I.—A. M., driver, 33 years, U. S., white. About a year ago began to complain of frequent urination and pain at the end of urethra. Nine months ago had an attack of hematuria. No stricture; urine contains few leucocytes, no blood or casts. Cystoscopy reveals no stone, no ulcer, very slight cystitis. Left ureter catheterized; right ureter, catheter was obstructed about one inch from opening. *X*-ray examination is negative. Injection of tuberculin gives a positive reaction.

December 8, 1908, nephrectomy was performed. The right kidney contained pus and multiple foci of tuberculosis. Convalescence was at first rapid, but the temperature remained around 100°. On December 18, the patient was out of bed and up about the ward.

On January 11, 1909, the wound was found to be gaping on account of insufficient union. On January 14 the wound was cureted; it was filled with unhealthy granulations. The stump of the kidney was explored, but no pus pocket was found. A piece of muscle was excised, and the pathologist reported this tuberculous. The patient grew weaker, the wound failed to close, tuberculous meningitis developed and death occurred on January 29.

Case II.—S. A. L., medical student, 29 years of age, has had attacks of renal colic, beginning six years ago, and occurring at intervals of days and months. He passed a small stone recently. The urine contained pus and blood. In January, April, and June he had attacks of severe renal colic.

In June, 1906, an *x*-ray examination showed a suspicious shadow. In August a guinea pig was injected with urine from bladder. The pig was autopsied and showed tuberculosis.

On cystoscopic examination the bladder was found to be healthy, except for slight ulceration at the site of the left ureter. The catheter could not be passed into the left ureter. Right ureter was catheterized and the urine showed no pus. A guinea pig was injected with urine from right kidney and autopsied. It showed no infection.

In October the patient had lost weight and strength; looked and felt badly. He was cystoscoped again: Left ureter, catheter entered half an inch and was obstructed. On the right side it entered easily and the urine was perfectly normal.

On October 5 nephrectomy was performed and the left kidney was removed; no calculus was found; about 3 inches of ureter was removed. On passing probe into ureter a grating sound was noticed, but the probe passed the obstruction and entered the bladder. The kidney was found to be riddled with miliary abscesses.

On October 23 he left the hospital and on January 4, 1907, had gone up to Loomis' Sanitarium, at Liberty, N. Y. He weighed 124 lbs. The sinus was still open, but there was little discharge.

On February 1 he had gained 17 lbs. and was in better condition than he had been for years. The sinus was still open but closing.

During 1908 he was in good health and continuing his medical studies. A condition which still prevailed in October, 1909.

Case III.—J. L. M., clerk, age 26 years, had always been perfectly well until symptoms of cystitis appeared in December, 1907. He then noticed that he had to get up every night to urinate. There was no pain nor discomfort. He grew progressively worse and had to pass urine every few minutes.

On March 20, 1908, cystoscopy was performed under anesthesia. Many ulcerations were seen around left ureter, which could not be catheterized. The right ureter was catheterized. In the urine there was no pus, moderate amount of blood, and no casts. Urea gr. v. to the ounce.

On March 21, the bladder urine was examined and showed a moderate amount of pus, but no blood, and urea 7 grs. In both specimens no tubercle bacilli was found with the microscope. He had great pain in the right side, spasmodic and cramplike for three days after catheterization; also incontinence of urine. The tuberculin reaction was positive.

Guinea pigs were injected. The bladder urine showed tuberculosis. The right kidney urine was negative.

On April 2, nephrectomy was done. The left kidney was a mere shell riddled with multiple abscesses. A large cyst at the upper pole was filled with urine. The wound was closed around a drainage tube. Recovery was uneventful. On May 6 a fistula was still present where the drainage tube was placed. He was going to the country.

On June 1 he could hold urine one hour and had gained weight.

In October, 1909, he has position as shipping clerk on a dock in New York Bay; has gained 23 lbs. in weight; the appetite is good; he feels strong and well; the sinus is healed. The urine still contains pus and is passed every half hour, obliging him to wear a urinal most of time.

Case V.—E. C. D., architect, 27 years; his mother died of phthisis. In childhood he had pyothorax. Six years ago had testicle removed for tuberculosis. When eight years old he had an attack of sharp pain on left side of back, which lasted two hours and was followed by similar attacks on an average of at least one every two months. There was one quiescent period of six months, five years ago. There was a history of passing gravel, pus, and blood; seven years ago he had a severe hemorrhage from the kidney for the first time. He kept about his work, in spite of attacks of colic, until eight weeks ago; then the pain began to be almost constant, requiring morphine grs. 1/4, three or four times a day to control it. He lost about 30 pounds in weight. The urine was passed frequently, with tenesmus, and much pus.

On October 20, 1906, he was admitted to Long Island College Hospital. An *x*-ray examination revealed no shadow. The cystoscope showed a cystitis; the right ureter was easily catheterized and appeared normal. There were ulcerations about the left ureter and it could not be entered. The right kidney urine showed no pus, a few blood cells, and a few cells from pelvis of kidney, but no casts or crystals; urea grs. 9¾ to oz.; a trace of albumin from blood; a trace of sugar. Phloridzin was injected. The bladder urine, in 24 hours, amounted to 76 ozs. It was acid, S.G. 1909; pus 3½ per cent.; albumin 2½ per cent. by volume; no sugar; urea 3.07 to the ounce; 281 grains total. There were no casts or blood. The pus was free

in form of clumps and shreds. There were a few cells from the pelvis of the kidney, but no crystals.

The prostate was enlarged and lumpy. In the lungs there were rough breathing and moist râles at apex.

Left nephrectomy was done. The kidney was destroyed and converted into a sac communicating with an enormously distended ureter, filled with mixture of pus and urine. The kidney was cut off from the ureter and the edges of the ureter were stitched to the wound and a drainage tube introduced.

November 15. Recovery has been uneventful. The patient left the hospital in two weeks, and is now walking about and has been advised to go to Brentwood Sanitarium.

March 15, 1907. He has gained 25 lbs., appears well and strong and the sinus has entirely healed. Dr. Arrowsmith found evidences of consolidation in lungs in November, which have now almost entirely disappeared.

1908. He is in good condition, has bought a farm in the country, and is doing the work on it. The sinus closes at times and pus accumulates in the dilated ureter, giving rise to pain. When the sinus opens and discharges, the pain is relieved.

1909. The condition is unchanged.

The following case represents the early and inefficient modes of diagnosis and treatment of tuberculosis of the kidney which were employed a few years ago:

Case VII.—H. A. In December, 1900, the patient began to complain of frequent urination, with a little blood and some pus in the urine. He was treated by bladder washing, but was not benefited and the frequency of urination increased. At present, he passed water every three-quarters of an hour and wore a urinal constantly.

April 8, 1901. An examination was made with a searcher. No stone was found. The cystoscope could not be used, as the bladder capacity was only 2 ozs. The microscope showed pus and staphylococci, but no tubercle bacilli. The prostate and vesicles were not enlarged. An external urethrotomy with prolonged drainage and bladder washing for one month resulted in a good deal of improvement, and in four months' stay in the country he has gained 15 pounds in weight and passed water four times a day and once at night.

In October, 1902, the condition remained about same. The urine was loaded with pus and of acid reaction. The cystoscope was used and demonstrated a stream of purulent urine issuing from the left ureter, with a swirl of clear urine from the right. The bladder showed a marked cystitis. A separation of the urines was made by means of the Harris segregator, with the following report:

Right kidney: a few pus cells from the pelvis of the kidney; a few uric acid crystals and cells from the tubules; urea 0.011 gram; reaction acid.

Left kidney: a moderate amount of pus; a large number of cells from pelvis of kidney arranged in large sheets and masses; a large amount of kidney epithelium; some uric acid crystals; urea 0.015 gram; reaction acid.

Sample of bladder urine: There was 9 per cent. of pus by volume. No tubercle bacilli and very few bacteria were present; only a few bacilli and cocci were seen.

October 13. Nephrotomy was performed on the left side. No stone was found; a tube was introduced and the kidney was drained.

November 25. Kidney still draining through the tube. Microscopic examination of urine drawn from tube in pelvis of kidney showed a few stray leucocytes but no pus.

May, 1903. The patient had tuberculosis of testicle and seminal vesicle. The testicle was removed The fistula into the kidney was still unhealed.

November, 1905. He returned for advice after spending one and a half years in the country. The fistula in the back was healed, but he had painful and frequent urination and dull ache in the region of the left kidney.

January 4, 1906. Nephrectomy of the left kidney was done and a large pus kidney (tuberculous), almost all of whose tissue was destroyed, was removed.

February 1. He left the hospital, with the wound in good condition. The prostate felt lumpy and was tender. The old fistulous track in perineum opened spontaneously. Fistula in back still persisted. The right apex of the lungs was suspicious. He was sent to the country to lead an out-of-door life.

March, 1907. The patient had lived on a farm and was able to do light farm work and was in good condition, although there were distinct fine râles in the right lung. The perineal fistula still opened occasionally. He urinated frequently and involuntarily, so that he had to wear a urinal.

June, 1909. The patient was well and comfortable and able to do light work on the place.

The object in representing this case in full is to show that without the modern methods of catheterizing ureters and demonstrating the tubercle bacilli by animal inoculations or vaccination, the diagnosis of tuberculosis of the kidney is extremely obscure. In the absence of an exact diagnosis, temporary palliative surgical operations such as external urethrotomy and drainage of the bladder for cystitis, establishing a fistula into the pelvis of the kidney with prolonged drainage were employed, instead of at once removing the focus of tuberculosis by the radical operation of nephrectomy. Not having done so, the tuberculosis extended from one kidney to the bladder, prostate, and seminal vesicles, and finally to the lungs. After removal of the diseased kidney, a general improvement in all the tuberculous deposits took place, and to-day the patient is in a very comfortable condition and is able to support himself.

Case IX.—Mary W., married, 31 years, has had three children and no miscarriage; has always been well and healthy. Her mother died at forty of typhoid fever. Ten months ago the patient was troubled with painful and frequent urination and tenesmus. She complained of frequent pain in body, particularly on the right side of the abdomen. Appetite was poor, the bowels irregular. She lost weight and strength; had no cough, but was feverish at night and had night sweats. Seven months ago she consulted a physician.

The urine was pale and acid. It contained shreds, a trace of albumin, and casts, but no sugar. Tuberle bacilli were found.

Examined with the cystoscope, the bladder mucous membrane was covered by scars and granulomas; both ureteral openings were narrowed.

Both apices of the lungs were affected. There was pain on the left side of the abdomen, growing progressively worse. The symptom of greatest

annoyance was the pain on the left side of the abdomen.

On October 16, 1906, she was admitted to Long Island College Hospital. She was emaciated and weak. The temperature was elevated. The right kidney was enlarged and easily palpated. On cystoscopic examination the bladder held 3 or 4 ozs. There were ulcerations about both ureters making catheterization difficult. The right kidney urine (Oct. 30) contained .01 per cent of pus; no casts or blood, and urea, grs. 2¼ to the ounce: the left kidney urine (Oct. 28) contained 0.01 per cent. of pus, no casts, no tubercle bacilli found, urea grs. 6.1 to the ounce. The guinea pig injected with urine from the right kidney after three weeks was found to be extensively affected with tuberculosis. The pig injected with left kidney urine was also affected, but less so. Nephrectomy was performed on the right kidney. It was very adherent, and much enlarged; the wound was closed with drainage. The kidney showed a large saccular dilatation at one pole filled with purulent urine; the capsule was adherent, and the outer surface studded with tuberculous nodules.

On November 15, two weeks after operation, the temperature was 101° or 102° in the evening; the urine 40 to 50 ounces and purulent. The pain in the left side was relieved, but the patient complained of neurasthenic pains in chest and region of wound. After leaving the hospital she had a good deal of pain, but less than before operation. She had typical tuberculous temperature as high as 102° and a profuse discharge from the wound. In January the condition grew worse and the existing sinus was enlarged to permit better drainage. She had a constant dull pain in lower part of wound. In the middle of January the patient had an attack of la grippe, with a temperature as high as 103.6°, could not retain food, had cough and night sweats, and her condition seemed serious. This attack lasted three and a half weeks, and since that time she has steadily grown stronger, has had better appetite, a normal temperature in the morning and at 8 P. M. she was now able to hold water two or three hours during day, but at night passes urine every half hour, but says her urination is only slightly painful as compared with the condition before her operation.

April 1, 1907. She left the city to go to the mountains.

1908. The patient lived four months in comparative comfort, and finally died.

Case XI.—C. T., single, born in Italy, a laborer, aged 26 years. The patient's former history was indefinite, as he spoke little English. He was sent to the hospital from the immigrant service with an infected toe; after this was healed he still continued to run a temperature 99° to 100.5°, and began to complain of frequent and painful urination. He was referred from the medical service after exclusion of typhoid, complaining of pain in the lumbar region, and tenderness over this part, but the kidney was not palpable. The urine contained a small amount of pus, no sugar or casts, urea gr. 7 to the ounce, and epithelia from the bladder. By cystoscopy, a very slight degree of cystitis was seen. The right ureter was catheterized, the urine showing a few more pus cells than normal. The left ureter also was catheterized and the urine was normal. The right side urine contained urea gr. 7 to ounce, and the left side urine, urea gr. 5 to ounce. No tubercle bacilli were found.

December 2, 1908. The tuberculin reaction was negative. Owing to the general condition, pain, temperature and past history, operation decided upon, without waiting for pig inoculation.

December 3. Nephrectomy was performed on the right side and a tuberculous abscess found in the upper pole; this had ulcerated through to the capsule, seemingly quite recently, as there was about one dram only of pus in the capsule, which was adherent partly and torn at this point on removal from the kidney. There were small tuberculous areas elsewhere throughout the kidney.

On December 4 he had reacted well from shock; temperature, 101°.

December 29. Comfortable convalescence.

January 11, 1909. The wound had healed; the patient had gained flesh.

January 19. Felt well and strong, had no fever. Discharged from hospital.

32 Schermerhorn Street.

THE CHAUFFEUR'S FRACTURE.

By WILLIAM S. THOMAS, M.D.,

NEW YORK.

SURGEON-IN-CHIEF, OUT-PATIENT DEPARTMENT, ST. LUKE'S HOSPITAL.

Modern machinery brings its special types of occupation diseases and among them the chauffeur's fracture, which is common in the experience of many surgeons, though perhaps there are not many who look upon these cases as other than those of the ordinary Colles' type. Fractures of the carpus, metacarpus, and phalanges are sustained by chauffeurs from the sudden and violent reversal of the starting handle of their automobile engine, but these are comparatively infrequent lesions in this connection. The type of fracture most commonly observed among chauffeurs and described below is a subvariety of the ordinary Colles' fracture but forms a distinct clinical entity.

When an automobile engine stands unused there is a gradual change in the proportions of air and gasoline vapor which fill its cylinders so that the mixture loses its explosive character. For the engine to turn the shaft automatically, fresh explosive mixture must be sucked into the cylinder by the motion of the piston before it is of any use to apply the igniting spark. To accomplish this suction no method has as yet been devised save for the shaft to get its first turn by man-power. It is during this starting turn by hand that the chauffeur's fracture is produced.

If the explosion is timed to occur in the cylinder before the piston reaches its highest point, or, in other words, if the spark be advanced, the said piston will be pushed down so as to turn the shaft and crank backward suddenly and violently. The motion of the crank-handle is thus reversed with a pressure of from 40 to 80 pounds to the square inch. If a human hand be pushing down with force upon this crank-handle at the time it is suddenly and violently pushed up against the said hand, something unpleasant may happen to the owner of the hand. If the back-kick of the handle occurs during its ascension it will be suddenly pushed downward, straightening out the fingers and releasing itself from the grasp. Under these circumstances no harm will be done unless the handle fly backward quickly enough and with force enough to strike the

forearm and break a bone by direct violence. At times, as shown in one of the skiagrams, the patient sustains a typical indirect fracture of the lower end of the radius from the back-kick of the handle which then flies around and smites his forearm, breaking by direct violence the shaft of radius, or ulna, or

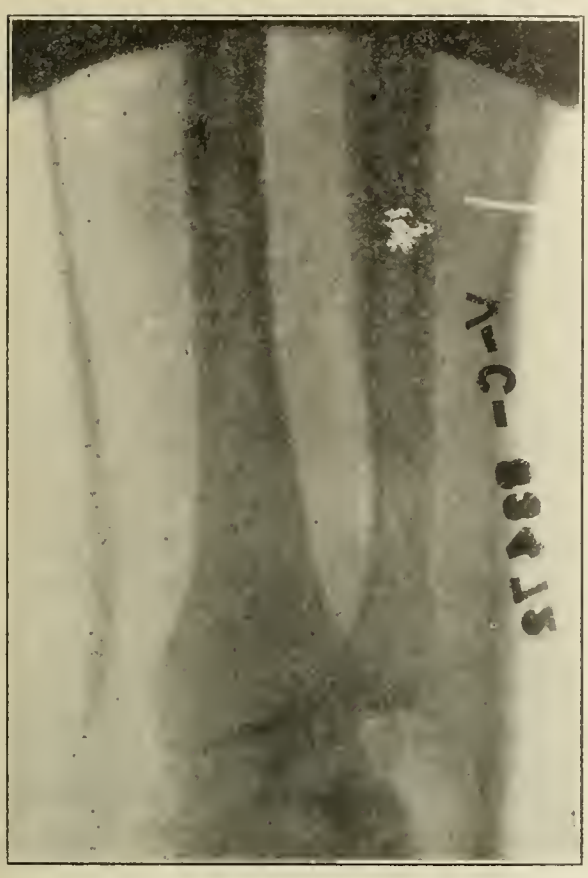


Fig. 1.—Oblique fracture of radius into wrist joint and fracture of its shaft in the same patient. A combination of the direct and indirect types of chauffeur's fracture. The styloid process of ulna is also ruptured.

both. This skiagram showing both types of chauffeur's fracture in the same patient was loaned by Dr. Ransom S. Hooker.

From our present standpoint the types of engines used in automobiles are alike except in the number of their cylinders. In one-cylinder engines there is but one point in the circle described by the crank-handle where it is possible for a back-kick to occur. In eight-cylinder engines the back-kick may occur at any one of four points in the circle. The automobile engines mostly in vogue are those with four cylinders. One might expect considerable variation of fractures sustained from force applied in such varying directions, but as a matter of fact the prevailing type of break is one occurring lower on the radius and with milder symptoms than those of the usual Colles' injury which has been acquired by falling upon the outstretched palm.

Fracture of the styloid process of the ulna is so frequent a concomitant of the ordinary Colles' lesion that it must be considered typical. Stimson, in his classic text-book on fractures and dislocations, states that this complication occurs in 10 per cent. of all cases of fracture of the lower end of the radius. Scudder of Boston puts the percentage at 80. I find among my own cases, where accompanying skiagrams have obviated the possibility of error in diagnosis, that in all cases of fracture of the lower extremity of the radius exclusive of incomplete and chauffeur's fractures, this avulsion of the styloid process of the ulna has occurred in 71 per cent. But it occurs much less commonly among the cases of typical indirect chauffeur's fracture. I have found it present in but 7 out of 30 cases or less than one out of 4.

Many chauffeurs are young adults and one would expect to find these low radial fractures among them coinciding more or less regularly with the line of union of the epiphysis with the shaft. But it does not often do so. Ossification of the lower end of the shaft of the radius is completed anywhere between the 18th and 21st year, but long before this age is reached we find fractures in the neighborhood crossing this epiphyseal line and even paralleling it.

The chauffeur's fracture is usually either transverse or oblique into the wrist-joint. In the latter case it is the lower outer corner of the radial head which forms the fragment. Variations are seen as comminuted and incomplete fractures, but there are comparatively few cases showing marked radial displacement of the hand or severe silver-forked deformity. Where the lower outer portion of the radius is found detached it is evident that it has been avulsed by the wrenching of the hand which grasped the handle. The few writers on this subject are divided in opinion as to whether the mechanism of the fracture be one of impaction through the

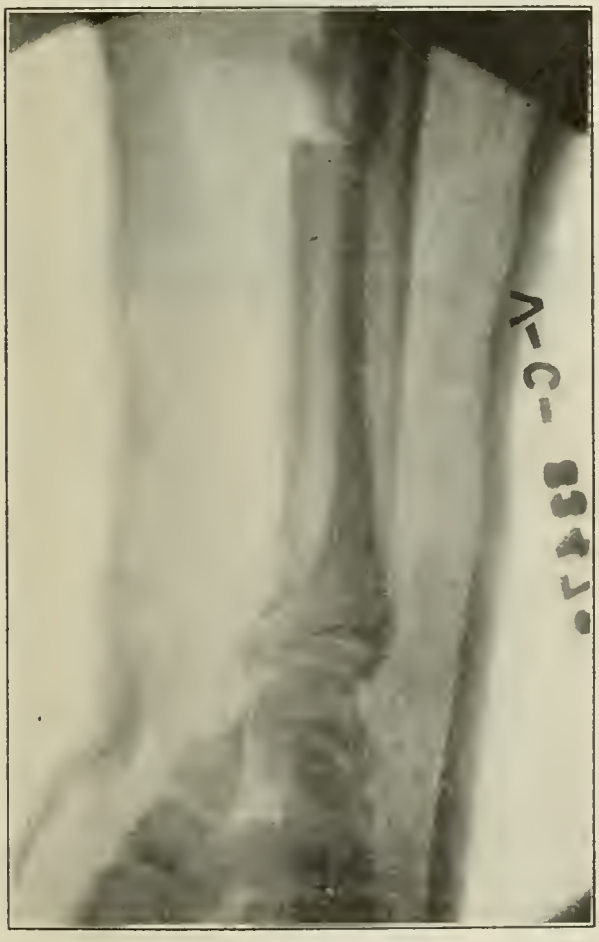

Fig. 2.—Lateral view of Fig. 1.

palm as in the ordinary Colles' type of injury or one of tearing off a fragment of bone by severe ligamentous wrenching. It seems clear to the writer that most of these fractures are caused by avulsion. As is so often seen to be the case, bone is torn rather than ligament where both have been subjected

to the same strain. Here the violence is evidently transmitted through the palm in a direction upward and outward while the thumb and fingers encircle the handle. The back-kick wrenches the hand violently in the direction of abduction and extension.

So mild are the symptoms in many of these cases that they are frequently considered to be sprained wrists, and do not reach the surgeon for several days. A typical case seen a day or two ago occurred in a chauffeur who drove his car many miles after the accident.

FIG. 3.—Typical chauffeur's fracture. Avulsion of lower outer segment of radius from back-kick of automobile crank-handle with slight deformity.

Treatment.—The chauffeur's fracture is a badge of carelessness. It does not occur where the ignition is properly adjusted so that the explosions in the cylinder will occur during the descent of the piston. In order to start the engine, if properly adjusted, it is but necessary to engage the crank-handle near its lowest point as it begins to rise and pull it up through a quarter of a circle, when an explosion in one of the four or six cylinders will start the automatic motion. If, however, an explosion occurs while one of the pistons is rising, thus constituting a back-fire, the handle of the crank will be jerked harmlessly out of the driver's hand. Should he be pushing the handle through the downward portion of its arc when the said back-fire occurs its violence may have added to it the strong muscular effort of the descending arm. As a matter of fact in actual practice it is very often necessary, in order to start the engine going spontaneously, to spin the handle, as it is called. This means a rapid revolution of the crank many times repeated. Under these circumstances a back-kick may come at any one of several points in the circle according to the number of the engine's cylinders.

Even though the spark be advanced and though it be necessary to spin the handle the danger of sustaining the chauffeur's fracture may still be obviated by attention to the proper method of grasping the handle. This should be grasped with the fingers and palm only, the thumb lying upon the same side of the handle as does the palm. The thumb should never encircle the handle. Should a back-fire now occur during the descent of the handle it will slide harmlessly up the palm.

Although so easy of prevention the chauffeur's fracture will continue to occur, and the surgeon should be ready to recognize the presence of fracture when a hasty examination might lead to the diagnosis of a less serious injury.

Immobilization of the forearm and wrist in anteroposterior splints is sufficient in the majority of cases. The fingers are left free and the patient is instructed to move them freely, for by so doing a return to the normal use of the hand will be hastened. Massage by one skilled in the art is of prime importance and should not be omitted. It may be begun immediately. The prognosis is good as would be expected in a class of cases occurring in young active adults where the deformity is but slight. The patient is usually back to work in three weeks with a wrist-band to be worn for a week or two after release from the splints.

SOME RECENTLY DESCRIBED SYMPTOMS IN SPINAL CORD TUMORS.

BY PEARCE BAILEY, M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE NEUROLOGICAL INSTITUTE.

ACCORDING to Stursberg,[1] whose analysis is the most careful and complete up to the present time, the percentage of cure in operations for spinal cord tumors is 32.2 per cent. This is gratifying in view of the inaccessibility of the tumors and the difficulties incidental to their diagnosis and localization. But one cannot read Stursberg's tables without seeing at once that many of the failures were avoidable and that much more may be expected from the operation. Delay in operating is the most conspicuous reason why the successes were not more numerous. It is also evident, in studying the question of spinal cord tumors generally, that certain new symptoms which have not yet found their way into text-books, must be reckoned with, and that variations in other symptoms not generally understood have interfered with prompt diagnosis. This paper will consider some of these.

We are so in the habit of regarding a spinal cord tumor as a local process, without effect on parts of the nervous system not directly connected with the region invaded, that symptoms appearing at a distance have often puzzled examiners when they tried to reconcile them with the spinal symptoms. Yet in a constantly increasing number of cases, tumors in the upper part of the spinal axis have been associated with choked disc and symptoms referable to the mid-brain and cortex. The development of these latter disturbances has been so associated with the development of the spinal symptoms that a relationship between the two was incontestable; and yet it is not a relationship of identical cause, as autopsies have shown that the brain symptoms, viz., the cranial nerve palsies, the choked disc, the delirious mental states, the headaches, and the epileptic convulsions, do not owe necessarily their existence to metastases from the spinal tumor nor from any destructive lesion whatsoever.

Such cases are explained on the assumption of an internal hydrocephalus. In many, the symptom complex of this condition was typical and complete; and in several the autopsy showed the dilated ventricles and oversaturated brain tissue of internal hydrocephalus, which had resulted from the closure of the spinal subdural space at the site of the tumor, either directly by the tumor itself, or through the membranous adhesions not infrequent in tumor cases.

Choked disc is the symptom which has received the most attention. Taylor and Collier[2] were among the first to analyze the condition. Most of their cases were myelitic, though they report one case of extramedullary and intrathecal myxoma and one other tumor case from literature. In one case of fracture of the vertebræ in the cervical region, there was swelling of the disc for five diopters. A spicule of bone was found at operation compressing the cord. This was removed and the choked disc rapidly receded. These authors found no cases in which the lesion was below the third dorsal segment.

In addition to choked disc, there may be many mid-brain and cortical symptoms. Nonne reports a primary intramedullary sarcoma which brought about well marked internal hydrocephalus. Before death there were palsies of the motor nerves of the eyes, of the facial and hypoglossal and of the nerves of deglutition, as well as epileptic convulsions.

Grund[3] reports a similar case in a child with a glioma of the lower cervical region. The cerebral symptoms consisted of headache, vomiting, slowed pulse, and choked disc. In this case the leptomeninges were also much involved.

The hydrocephalic symptoms in these spinal cases are usually late in development, but not always. Heubner[4] has reported a case in which the first symptoms were central—viz., headache, vomiting, unilateral, postneuritic optic atrophy, and nystagmus. The tumor consisted of six gliomatous masses extending from the lower cervical region to the lumbar region. Associated with it was a well developed chronic spinal meningitis. Cases such as this seem to favor the view that membranous adhesions quite as much as the tumor mass itself can shut off the subdural space and so inaugurate the hydrocephalus, an assumption which receives further support from what we now know of serous meningitis.

In all of the reported cases, the tumor has concerned the cervical region. But I am not prepared to go as far as does Taylor[5] in saying that choked disc has never occurred from tumors in the lumbar region. His case, which I saw in the early stages only, was an intramedullary sarcoma which began in the cauda equina and extended upward to the mid cervical region, proving fatal in seven months. In three months there were distinct mental symptoms, and in less than four months there was demonstrated a swelling of the optic discs. But at this time the spinal symptoms were limited to an area indicative of a lesion at the dorsolumbar junction, and symptoms referable to the cervical region did not occur until there had been headache and free vomiting. So it seems entirely possible that in this case the hydrocephalus had begun before the tumor had passed far beyond the upper confines of the lumbar region; a possibility to be taken into consideration if an unexplained choked disc or other symptoms of increased brain pressure should appear even when all the spinal symptoms point to a low lying lesion.

In 1903, Spiller[6] reported an operation upon a supposed spinal cord tumor at which no tumor was found, but which resulted in the evacuation of a subdural cyst. This communication proved very important, as by it attention was first called to the subject of serous cysts and circumscribed serous meningitis. Spiller's case has been followed by several others[7] of similar character. Bliss[8] has recently graphically described one as follows: The symptoms had been those of a spinal cord tumor following a trauma.

"The spines and part of the laminæ of the seventh cervical, the first and second dorsal vertebræ, were removed. The dura bulged irregularly at the upper and lower ends of the part exposed, seeming to indicate a constriction between. The dura was a darker white at the bulging points. The dura was slit centrally from below upward. A sharp spurt of clear fluid, which could not be distinguished from the cerebrospinal fluid, occurred. It seemed that the lower end of a sack had been opened, for the upper end ballooned up with cerebrospinal fluid, as it surged upward in response to the cardiac movements. When the dura was grasped by forceps and gently lifted, small bands of tissue were seen stretching between the dura and the pia. Very slight force with a dural probe sufficed to break these up, after which the ballooning process ceased. There was proliferation and engorgement of the vessels of the pia."

As far as is known, the cysts, which are subdural, consist in larger or smaller quantities of cerebrospinal fluid, collected in the meshes of the pia or between the pia and dura. They are not parasitic, differing from the parasite cysts in being not multiple but single, and in being much less apt to cause extensive erosions of the vertebræ. Nothing in the symptoms distinguishes these simple cysts from spinal cord tumors; and, in fact, they have all been found at operation undertaken for tumor.

No cause has been discovered for the simple serous cysts. Some cases have followed trauma. It is possible that some of them are merely a complication of a spinal cord tumor. At operations at which they are found, therefore, the operation wound should not be closed, after evacuation, until as much exploration as possible has been done. It is in these simple cysts that the best explanation is found of spontaneous recovery from spinal cord tumor, such as is reported by Henschen.[9]

Another condition often found in the neighborhood of tumors (6 times out of 22 of Krause's spinal operations) is a circumscribed serous meningitis, or circumscribed subdural collections of cerebrospinal fluid in the immediate neighborhood of the tumor. This may interfere with correct localization particularly if the serous collection is above the tumor, as is apt to be the case; and lesions of this character seem to me eminently qualified to bring about an internal hydrocephalus.

The one significant vasomotor symptom which has not received much attention is edema. This has been observed chiefly in the lower extremities, in tumors of the lower segments of the cord and in cauda lesions. It has the general characteristics of edema due to kidney disease but is distinguished from it by the urine being normal. In one of my cases there was some edema of the ankles, with normal urine. But the edema may be very great. In a case seen in consultation with Dr. Frederick Peterson, the lower extremities were swollen to one-third of their natural size. It is not always possible to be certain that this edema is not the result of blocked venous return, although it is certain that no such cause is necessary. Schnoll,[10] before operating on a gliosarcoma of the sacrum, in which the edema of the legs was very great, did a laporotomy for the purpose of investigating the vena cava. These were found unobstructed and after removal of the tumor the edema disappeared with the other symptoms.

Since my report, in 1892,[11] of a patient who died from spinal cord tumor without having suffered severe pain, a considerable number of cases have been recorded in which pain was inconspicuous or late in appearance, or altogether absent. By greatly enlarging the possibilities this remarkable variation from the usual injects new difficulties into diagnosis. It must now be reckoned with that a slowly developing and painless compression of the spinal cord, without evident cause, may well be the result of a new growth within the spine; and all such cases challenge attention from the point of view of exploratory laminectomy. When pain is present, it is usually one-sided at first, is referred to some one of the spinal nerves such as a sciatic, an intercostal, or a branch of the brachial plexus. It occasionally appears as a referred pain and in the period which precedes paralysis, spinal cord tumors have been mistaken for pleurisy, for gall-bladder disease, for appendicitis, for angina pectoris, as well as for rheumatism or neuralgia. The pain may come on suddenly. Flatau[12] has reported a case in which the first symptom was a sudden pain in one foot, and Abbe[13] another in which pain between the shoulders, coming on suddenly after a game of golf, was the first sign of trouble. The pain is rarely constant at first; it may come on only at night or after fatigue; as the disease progresses, the pains take on a distinct neuralgic character. The attacks, which make life hard to bear, last for a few minutes or for several hours. They are repeated several times a day, or less frequently. There are often intermissions for weeks or months so that the patients cherish the delusion that they are cured. One patient was incapacitated for work for several months by the pain, and then was so far freed from it that he was able to resume his work for six months without serious inconvenience. Another, while under treatment for a supposed rheumatic affection, went to Marienbad. While taking the baths the pain stopped and the patient had several months of comfort and was led to believe that she was cured. There is considerable variation as to what starts the paroxysms of pain. They are often spontaneous, coming on without evident cause. They may be, also, intimately linked with movement. Many patients are comfortable except when a change of position, a sudden jar, coughing, and the like brings on the pain. These are the cases most apt to be mistaken for rheumatism for some time. Attacks of pain associated with movement are also seen in the spasmodic twitchings, which are apparently of reflex character.

IS MEDICINE FAITHFULLY MIRRORED IN MOLIÈRE?

By W. B. KONKLE, M.D.,
MONTOURSVILLE, PA.

Upon entering the lists in championship of Molière's fair fame, our first care will be painstakingly to fix the barriers. The establishment of limits is in any discussion a proper logical procedure; it is more than that in the development of our present argument—it is essential, it is imperative. Indeed, the setting of bounds in the way of discrimination and elimination will constitute the greater part of our task.

As a first step toward inclosing the field it may be remarked that portrayals of the medicine of the seventeenth century, and not of twentieth century medicine, should be looked for in Molière. Truly enough human nature is always the same; but human knowledge grows, and human manners change. Man is forever man, but men forever vary. And just so doctors and physic are not fixed quantities; the several epochs have produced their peculiar types, or their divergent transmutations of type. Satire cannot be prophetic; it is necessarily realistic and historic—it deals with the "here" and the "now." Aristophanes draws his caricatures from the Athens of his day—it is Socrates and Cleon and Euripides, and Athenian sophism and demagogism that he shows us. And so Molière in his travesties of medicine finds his subjects about him—the matters medical compassed by his art appertain to his France and to his era.

Let it be borne in mind that seventeenth century medicine was a thing very different from twentieth century medicine. We are yet far, far from a consummation, but, nevertheless, we are at a point appreciably nearer the goal. And this is said in no

self-laudatory or vain-glorious way. It is asserted with full recognition and appreciation of the basal work wrought through the dragging ages under conditions and against obstacles and amid restrictions whose overcoming was signalized alike by the worthiest achievement and by the most splendid heroism. Indeed, the triumphs of the past form the keenest spur to our endeavors and the strongest warrant of our hopes. And inspired by conquest we will go forth to conquer. We will investigate and investigate, and analyze and analyze, and differentiate and differentiate, until at last ours will be the crowning victory—until we shall shout our final "eureka." Of course, about that time Gabriel may blow his horn, in which case there would remain to us only our labor for our pains. But no matter; is not victory, at any rate, often its own sole reward?

Medical science had, truly, not got very far on at the middle of the seventeenth century. Some progress had been made to be sure, but the situation presented more of potentiality and promise than of fact and accomplishment. Speculation still vastly eclipsed investigation—outranked it and outweighed it. Gross anatomy had reached a structural stage foreshowing its final proportions. Physiology and pathology were largely a conglomeration of doctrines, whimsical, mystical, ephemeral. A few remedies of utmost value had been empirically discovered and proven, but the materia medica was a sad jumble—an indistinguishable mass of chaff and wheat with the chaff greatly preponderating. Therapeutics partook of the fancifulness and vagueness and instability then characteristic of pathology. Chemistry was barely being evolved from alchemy. Chemistry of the organic world, as we now know it, was then *terra incognita*. Histology, that foundation of the foundations of medical science, was an embryo in the womb of time. As for surgery, it had won considerable prestige and dignity, especially in France, where, according to Pagel, an enduring primacy had been secured for it three centuries earlier by Guy de Chauliac. But surgery is first an art, and only afterward a science.

Reference to a few specific incidents may give us additional light. Jean Fernel's "Medicina Universa," though produced at an earlier period, maintained its vogue in all Europe well up to the time of which we write. In a section of this work treating of how to proceed upon visiting a fever patient, occurs this passage: "And, moreover, it is necessary to see by the proper signs which are manifest in his body, whether it is pure or impure; if it is impure, in what region of the body resides the vicious and morbid humor?" Scarcely a *renchérissement* upon that is the following passage from Molière's "L'Amour médecin.":

"Doctor Tomès—'We have looked the patient over sufficiently, and without doubt there are many impurities in her.'

"Sganarelle—'My daughter impure?'

"Doctor Tomès—'I mean to say that there are many impurities in her body, a quantity of corrupt humors.'"

One of the most virulent and implacable of the antagonists of Harvey was Jean Riolan *fils*, dean of the Faculty of Paris, and long the head of medicine in France. Through his influence the teaching of Harvey's doctrine in lectures was prohibited. True, the stigma of this outburst of bigotry is somewhat palliated by the facts that one of Harvey's earliest and warmest advocates was Descartes, and that *le Grand Monarque* later commissioned Dionis to teach the circulation at the Royal Garden expressly instituted to counterpoise the ultra-conservative action of the Faculty. Strange to say, Harvey made common cause with Riolan against Jean Pecquet. Riolan and Harvey in alliance! Could there be more forceful illustration of the fog and chaos pervading the medical science of that day?

Jean Riolan *père*, himself, had been twice elected to the deanship of the medical faculty upon the very strength of his devotion to classical authority. No man ever wore more proudly the chains of mental servitude. He became the chronicler of his own abject thralldom when he wrote, "I prefer to err with Hippocrates, whose knowledge has been so long approved by all nations, than to be right with Paracelsus, that impious pseudo physician." In "Le Malade imaginaire" Molière gives us this sketch from the mouth of a doctor speaking of his son, who is an advanced student of medicine—"Above everything, that in him which pleases me, and in which he follows my example, is that he is blindly attached to the opinions of our ancients, and that he has never wished to comprehend or hear the reasons and the experiments of the pretended discoveries of our age, concerning the circulation of the blood and other notions of like stripe." Can it be that Molière has here wrought into his immortal art the very Jean Riolan *pere et fils?*—or has he simply seized and fixed forever the features of a type to which belong Riolans and Riolans a numerous company?

Upon the occasion of the wounding of the warrior-surgeon, Machaon, Aesculapius' son, at the siege of Troy, Homer makes the hero, Idomeneus, say, "A physician is worth many another man." And true has this been all the way down from the day of Chios' sightless bard. When it is a question of a bodily ill or hurt the doctor, with all his shortcomings and too-far-goings, yet has ever been the best man in the field. A bit of Frankliniana sets forth how at a meeting of a medical society of which he was president, Sir John Pringle was asked for his opinion as to whether on the whole physicians have done most good or harm. Sir John replied dryly that it depended on whether under the appelation were to be included old women—if they were, then had physicians done more good than harm; otherwise, more harm than good. Let us at least partially draw the sting of Sir John's quip by insisting that if without the credits of the grannies added thereto the score is against the doctors, still is it a better record than could, or would, have been made by any other class of men. In the treatment of disease and in the management of sick people, medical men have at any period been in advance of the contemporary laity. In no science has any one so broken away from the plodding ranks of humanity that he by a sudden and single flight reached the ultimate goal. The greatest souls of earth have, after all, been only leading souls. The Star of Bethlehem went just before the Wise Men of the East. After the unrolling of centuries the Galilean came; but He had his forerunners, and about His age in a constellation of glory cluster Hillel, Gamaliel, Philo, Apollonius, Cicero, Seneca, Epictetus.

But what faults and fallacies and follies are to be imputed to medical practice throughout its various stages! And how grossly empirical has it been! In very self-exculpation, self-justification, let us deprecate the equivalent use of the terms empiri-

cism and charlatanry. Then, too, had doctors only stopped short always with what they knew! But that would have been to reveal the narrow limitations of medicine. Sophocles has Ajax saying, "An able physician does not have recourse to magic chants for a malady which the knife alone can cure." Nevertheless, he has been ever prone to ring in the "magic chant" at any rate in a supplementary way.

The absurdities and monstrosities of medical practice were, however, inevitable. The application of a science logically comes last—is a climax; in medicine, of necessity, it was first. Doctors had to practice medicine for a livelihood while they developed it, in order that they might develop it, as a science—to exist by it while they were creating it—at blossom time to hypothecate the fruit; a case of *manger son blé en herbe* with a paradoxical signification. Besides, people demand doctors that doctor. Very few have been those to exclaim with Job, "Ye are all physicians of no value." Most folks, rather, are like King Asa of Judah, who, when he was "diseased in his feet," "sought not to the Lord, but to the physicians."

And that will-o'-the-wisp of reasoning processes, *post hoc ergo propter hoc,* so illusive and delusive and elusive, how by it has medical practice been led again and again upon treacherous quicksands and into desert wastes! Jack Tar whistles for a wind; and whistles and whistles until the wind comes; and thinks it came because he whistled for it—that is the logic of a preposterous proportion of medical expedients. From the savage priest doctor with his dances, incantations, and charm-rattles, up to the grave and dignified *medicinæ doctor* with his cap, cloak, and cane will the impeachment hold—up to that point, and beyond it; but how far beyond must not be told.

The systems of medicine, various and multifarious, have one after another led medical practice from captivity to captivity; so much so that anon the greatest clinicians, in disgust and dismay, have been wont to sweep them aside, and to hark back to the naturalism of Hippocrates. In many instances these systems have not even reached the plane of tentative working theories. Some have contained germs of truth, or partial truth; and had they been granted only relative and subordinate sway, might have tended to purely benign ends; but reared to absolute and despotic reign, they proved veriest Molochs and Juggernauts.

And were the crudities, the puerilities, the absurdities, the vagaries, the monstrosities, and—shall we say it?—the atrocities, of speculative, quasi-rational, embryo-scientific medicine, were these ever more salient, more glaring than at the middle of the seventeenth century? A giant early in those days was van Helmont with his misty doctrine of the Archeus. Another of the period was de le Boë with his iatrochemicalism. Yet another was Borelli with his iatromechanicalism. The consistent practice of schools reared upon such foundations could not escape being largely grotesque and pernicious. But there, too, was Sydenham, the bed-side doctor, the clear-sighted, the level-headed. And Sydenham—Sydenham?—yes, Sydenham!—Hippocrates *redivivus*!—gauged the action of mercury by the amount of saliva secreted, and advised in volvulus the application of a live dog nakedly to the belly!

Considering Molière, himself, one must discriminate between the man and the playwright. At once let us frankly admit with Sainte-Beuve that he did not always do so well as he taught—that his life was not so lofty as were his ideals. But it is the writer that concerns us in this discussion; not the person. Cloud and tempest and defilement appertain to the lower earth. The heavens are always bright. The stars are everlastingly the same. And Molière's genius speaks from its home in the upper ether. And as reflection ranges the dizzy distance between the mortal weakly walking and the immortal sublimely soaring, David's lines come to mind—"Though ye have lien among the pots, yet shall ye be as the wings of a dove covered with silver, and her feathers with yellow gold."

From the standpoint of strict reason and relevancy, Molière, the man, might properly here pass out of sight. A conspicuous circumstance will not permit such a dismissal, however. In spite of the hard thumps he gave them Molière seems to have lived on good terms with the medical men about him. He generously used his credit with Louis to gain for the son of his own physician a state appointment. But at times and in places doctors have allowed themselves to show pique toward one of the truest monitors medicine has ever had—the creator of that irresistible ridicule, so life-giving because so death-dealing. At one aiming to correct them they have made faces as at a tormentor; and have cast in his teeth the peevish retort, "You, yourself, are not any better than you ought to be." The patient upbraiding his surgeon with deformity! These performances entitle Molière to apologists within the ranks of medicine. With such incitement to speech Horus, himself, scarcely could keep silence.

Perhaps the most direct and pertinent apology of Molière's faults and failings would be the laconic statement that he was a Frenchman. Your Frenchman is forever the despair of the rest of the race. He is so unscrupulous in his unfaithfulness, so polished in his profligacy, so dignified in his debauchery, so saintly in his sinning, so dainty in his deviltry, that to people outside of France he is an inscrutable mystery, an eternal *double entente.* And, yet, what were the world had there been no France! Molière, the genius, belongs to all time and to everywhere. Molière, the man, was the average, typical Frenchman; no more, no less.

But other nations have alike shown ethnic traits equally shocking and puzzling to outsiders. Rome's very first foundation stones were laid in a brother's blood. Rome's history is a succession of gory tablets. Sulla was not a monster; he was incarnate Rome. To Rome the safe foe was the dead foe. Jugurtha's fate was damnable; but its execution was Roman. Claudius' pardon of Caractacus was illustrious; but it was not Roman. And, yet, we cannot understand how a Julius Cæsar could tolerate the ignominious, cruel death of the heroic Vercingetorix. We cannot understand how a Titus could devote indiscriminately humans and brutes by thousands to slaughter in the arena. We cannot understand how a Marcus Aurelius could have sanctioned a religious persecution which rivaled that of Nero.

Greece was the land of free sentiment and free fancy. To be a Greek was to be a universal beauty-worshiper. Perception and enjoyment of the concretely beautiful are essentially functions of sensation; and sensuousness merges by easy degrees

into sensuality. So we could comprehend mere laxity and license of morals among Greek communities. But we cannot understand how Greece, enlightened, glorious Greece, could lapse down the grade of degredation, degeneracy, depravity, perversion to the lowest level of unnatural vice. We cannot understand how many of her foremost men could have been addicted to such vice, nor how it could have been condoned, even extolled, by some of her most famous philosophers. We cannot think of the truth-loving image-maker of Athens, the sent of God to the Hellenes, as the approving and sympathetic counselor of a professional courtesan. We cannot think of the lord of the Academy, broad of intellect as well as broad-shouldered, in the capacity of an advocate and eulogist of monosexual love.

And so marvels might be cited in others of the various civilizations ancient and not so ancient. But let us pause to look at ourselves—us of anglosaxonism by descent, or by choice, or by destiny. Are we, too, not a riddle?—we who have made of puritanism a term coequivalent with pharisaism and hypocrisy!—we, the tax-gatherers of the whole earth, who, when we do happen to go up into the temple to pray, instead of smiting upon our breasts and begging for mercy, in phylacteries and wide-hemmed robes borrowed and ill-becoming us, standing bolt upright, thank God that we are not like other men!

Satyr-like souls there are, revolting prodigies of licentiousness, whose supremest conception of blissful existence chiefly comprehends harlots here and houris hereafter. They have been confined to no time, no place, no caste, no guild. They have sat on thrones and in chairs; and they have, too, loomed large in the field of world-literature. But Molière was not one of these. He can be charged with only mild libertinism—in France a soft impeachment. Voltaire killed the calumny that sought to sully Molière's name with the shame imposed upon Lot by filial solicitude, and imputed rightly, or wrongly, to the Blue-Beard of English royalty.

In sooth, Molière was guilty of the folly of marrying a young wife at an age when he might have more profitably been thinking of something else. For that he had a monumental example in the protagonist of tragic drama, the author of the *"Œdipus Tyrannus."* Molière was the victim of matrimonial infelicity, rather than the originator of it. And let us remember that the roll of husbands unwisely or unluckily wed also bears such names as Socrates and Nicon, father of Galen, and John Milton and John Wesley. Truly "a prudent wife is from the Lord."

As stated, this notice of Molière, the man, is intended to be an apology. We shall attempt no panegyric. Much might be said of his merits—of how he failed like a man, and conquered like a god. We might laud his virtues—might speak of his bigness of heart, and of his greatness of soul. Big hearts are plenty; great souls are nobler, and are rare. We might show how the fires of adversity and suffering but heightened the purity and luster of the gold that was in him. Aeschylus says in the "Agamemnon," "This law is from Zeus—at the price of pain, knowledge. Drop by drop until we sleep falls upon our hearts the sharp remembrance of sorrow; and in spite of us wisdom comes." And so Molière toiled and suffered and endured. And we imagine his heart-strings vibrating in many a weary, dreary hour to the sentiment of those lines from the "Wanderers Nachtlied" of Goethe—"Ah! I am tired of striving! What shall avail all pain, all pleasure? Sweet peace! Come, ah! come into my breast!"

Doctors are men as well as doctors—that is another pertinent point of discrimination. Most human of the human are they. DaCosta once said to his class in giving his Christmas God-speed, "He who is not in full sympathy with the humanities of life is only half a man—indeed, he is only a third of a doctor." It is well that it is so. It is better to be loved as human than to be adored as divine—better for each, better for all. King Oedipus says to the seer, Tiresias, "To serve humanity is the most beautiful use that man can make of his art and of his power." To best serve men one must know men; and to best know men one must be a man. Massillon, he to whom the great Louis said, "In hearing some preachers, I feel pleased with them; in hearing you, I feel displeased with myself"—Massillon, when asked whence he derived his intimate knowledge of human nature, replied, "From my own heart." Schiller expresses the same idea thus —"Would you recognize yourself, observe how others do; would you understand others, glance into your own heart." Vauvenargues shades the thought thus—"We discover in ourselves what others conceal from us, and we apprehend in others what we conceal from ourselves."

The physician certainly belongs to the genus homo; but he is just as markedly a being of personality, of individuality, even of peculiarity. There are doctors and doctors; just as there are all sorts of other people. You have your long doctor, and your short doctor; your fat doctor, and your lean doctor; your slow doctor, and your brisk doctor; your taciturn doctor, and your garrulous doctor; your grave doctor, and your jovial doctor; and so on. There are queer doctors, too—doctors who are like some religious sects, that, in turn, are like some horses that have all the essential qualities of a first-class, high-grade horse, but are off color.

Now doctors, being at the same time so typically and so originally human, it is not strange that the eye of a poet like Molière, which

> —"in a fine frenzy rolling,
> Doth glance from heaven to earth, from earth to heaven,"

should often settle upon them as characters representative of human traits and human freaks. But to portray them thus is to show them as men; not as doctors. Van Laun declares that "Molière placed upon the stage nearly all the human passions which lend themselves to comedy and farce." In doing this what a numerous train of personages he drafts into service! Every walk of his life has furnished its contingent. And the same part is not always played by the same individual. Of course, Molière at the same time caricatured class faults: but he did it generally and impartially. Voltaire says that "he contributed to rid the public alike of self-important underlings, of the affectation of blue-stockings, of the pedantry of strong-minded women, of the robe and the Latin of doctors."

When Molière began his career as a dramatist the ribald, hyperbolical, roaring farce of Spain and Italy was in vogue. There he started. But genius walks beneath the wand of destiny. At that low level Molière could not tarry. Beginning with "La Jalousie du Barbouillé" and Le Médecin volant"

upon a plane all unworthy of his mission and of his powers, he led his art up and up until it reached the heights of "Le Misantrope" and "Le Tartuffe." Lapses and relapses are evident, which partly justify the severe stricture of Despréaux that he "allied Tabarin to Terence." But victory, not defeat, is the measure of the conqueror. By the criterion of his masterpieces, rather than of his marred products, should be fixed the rank of the creative artist. If Molière is not always Molière, neither are Æschylus and Corneille always Æschylus and Corneille.

Molière stands out in bold relief as a reformer. His literary instrument was broad caricature bordering upon burlesque. He was not of the class of La Rochefoucauld who, with a single massive projectile, well aimed and mightily driven, would rip asunder from stem to stern the rotten hulk of hypocrisy. He was not of the class of Pascal, who brought to bear against error until it was crushed, an unrelenting, inflexible, irresistible logic which, like "the mills of God," though it "ground slowly, yet ground exceeding small." He was not of the class of Voltaire, who with that graceful, diamond-pointed rapier of his, was wont to deliver through and through thrusts; when there would be a dart and a glint and a prick; and everybody would laugh, and nobody knew anybody was hurt; and, lo! wrong had received its death stroke. A right royal boxer was he, a Pollux, who in fair, open ring gave good, hard thumps until the faults and abuses and vices he opposed went down, nevermore to rear a respectable head. Joubert says, "Molière is comic in cold blood. He provokes laughter and does not laugh."

A *pensée* of Pascal runs thus—"It is dangerous to impress too much upon man to what extent he is like the beasts, without showing him his greatness. It is, again, dangerous to impress too much upon him his greatness without his baseness. It is yet more dangerous to leave him ignorant of both." In drama Corneille and Racine presented the ideal in man—depicted the potential dignity, nobility, glory of his being. Side by side with them wrought Molière. The function of his art was to produce the counterpart of that fair picture—perhaps we had better say the background of it—to throw into the scene the weakness, the meanness, the viciousness of man's nature. That Molière consummately did—did it for then and forever. And the enlightening, edifying value of his work will remain while on this little sphere of ours are reared and trained and tried and sealed archangels for the courts of God.

Satire in its application should be characterized by consistency, invariability, impartiality. It should treat all alike, and always alike; if it do that, no one person, or class of persons, has any ground for complaint. What a fool fit for bedlam would be the individual who should smash a distorting mirror because it made him look ludicrous, its sole design and uniform effect being to make people look ludicrous! The perspective and the ratio of Molière's caricature are always the same; concerning it there can be no particular grievance.

A comparative study of *la médecine* and *le médecin* in his plays and *la médecine* and *le médecin* as they actually existed at his day, reveals the fact that Molière had a clear discernment and an accurate comprehension of the weak side of matters medical. Howsoever it may be urged that he hit too hard and too much, at least it cannot be said that he did not hit in the right place. His keen discrimination in this way is significantly indicated by his silence as to surgeons. Although of lower caste, surgery as an art at that time was far above and beyond medicine proper. Molière's doctors are not sawbones. It was the scholasticism, the bigotry, the pedantry, the servility to authority, the swollen pomp and pageantry of medicine that Molière attacked. And then, and since then, other great lay thinkers have done the same—have done it more scathingly for having done it more seriously.

But that is not all. Doctors, themselves, have been, perhaps, the harshest critics of medicine—which is as it should be. Rabelais, our Rabelais, said, "Certain men, who are among physicians and pass for such, are found, if one searches them to the bottom, empty of knowledge, of good faith and of prudence; but full of arrogance, of envy and of uncleanness. They get their experience in killing people, as Pliny formerly made complaint about it; and by them one is menaced with more peril than by the malady itself." Such denouncing Ezekiels have arisen in our midst all the way down to our Autocrat of the Breakfast-Table.

When Blackmore asked him what medical authors should be taken as guides, Sydenham replied, "Don Quixote." In this oracle of Delphi, what wisdom lies hidden! If Cervantes, why not Molière? Let him have a perpetual place as a teacher of medicine. Thankful, rather than resentful, that he has written so much about us, let us study him deeply, humbly, appreciatively. Let us not be as were *les faux dévots* toward "Le Tartuffe." In his "Amphitryon" Molière makes Sosie say, "The lord Jupiter knows how to gild the pill." Molière himself does not gild his pills. But let us not, like children, reject his salutary doses because they have the flavor of the medicine. And from him we shall learn as scientists the lesson, half-concealed by cynicism, in this maxim of La Rochefoucauld—"The truth does not do as much good in the world as its appearances do harm there." And as men we shall learn to live like Philoclès of the "Télémaque," of whom Fénelon says, "He made greatness to consist not in self-aggrandizement, but in self-conquest, and in doing nothing base."

CHRONIC CONSTIPATION.*

By J. RUSSELL VERBRYCKE, JR., M.D.,

WASHINGTON, D. C.

It is impossible to give even a complete synopsis of so large a subject as chronic constipation in a short paper so I will confine myself to some of the main points of the etiology and treatment of the condition. These two are naturally to be considered together, since the treatment of constipation should never be purely symptomatic but by direct consideration of the cause or causes and removal of the same.

Probably chronic constipation is, on the average, more carelessly or irrationally treated than nearly any other symptom or pathological state. In formularies we often see prescriptions containing various combinations of purgatives and laxatives recommended for use in chronic constipation, these often being used for varying lengths of time without de-

*Read before the Georgetown Clinical Society, November 29, 1909.

termining the factors entering into the particular case, sometimes without a physical examination and without the conjunction of other and more curative measures. I have seen cases of this kind where endeavors to secure daily movement of the bowels, by means of purgatives only, has resulted in total inability to have a stool without some medicine. Recently I saw a young man who had suffered from chronic constipation for seven years, during the last five of which he had been treated solely *per os* with nearly all the various drugs, with the result that his condition became progressively worse, finally becoming entirely dependent on stronger doses of the medicines to produce any result whatever. After absolute removal of all purgatives and the institution of systematic local and general treatment his condition improved almost from the start.

Definition and Classification.—By constipation is meant the insufficient evacuation of the bowels, whether due to too small or too infrequent movements, more often the latter. The condition may exist by itself, may be symptomatic of another condition, may accompany another pathological state or may cause other troubles. The factors entering into the causation are legion. There may be one or several in a given case.

I shall classify the various varieties of chronic constipation as follows:

I. Mechanical obstructive constipation or obstipation; II. Non-obstructive.

A. Chronic constipation primarily caused by disease of other organs than the stomach or intestines: (1) Due to venous congestion of intestinal circulation (a) in organic disease of the heart and kidney; (b) in chronic pulmonary affections, asthma, emphysema, etc. (2) Due to impairment of secretions poured into the intestines: (a) in chronic disease of the liver, where the bile is affected; (b) in disease of pancreas. (3) Due to disturbance of innervation of intestines through disease of brain, cord, and nerves: (a) brain tumors, hydrocephalus; (b) chronic insanity; (c) tabes and general paralysis; (d) lead poisoning; (e) neurasthenia, hysteria, and hypochondria.

B. Chronic constipation caused by gastric disease: (1) Due to impaired motility of stomach (a) atony of stomach; (b) dilatation of stomach; (c) pyloric stenosis (cancer and ulcer). (2) Due to secretory disturbance (a) hyperchlorhydria; (b) chronic gastritis; (c) achylia gastrica.

C. Chronic constipation caused by, causing, or accompanied by other intestinal conditions: (1) Due to painful conditions, causing voluntary abstention from stool: (a) hemorrhoids; (b) fissure of anus; (c) ulcers of rectum; (d) chronic proctitis. (2) Due to changes in the mucous membrane impairing its irritability: (a) chronic catarrh of small intestine; (b) mucous or membranous colitis; (c) sigmoiditis; (d) atrophy after catarrh.

D. Chronic constipation unaccompanied by any organic lesion: (1) Due to pathological functioning: (a) spastic constipation; (b) spastic contracture of the sphincter without anatomic cause. (2) Due to imperfect physiological functioning (simple chronic constipation).

This classification is, I think, clear because of its simplicity. In parts of it I have followed Illoway closely. I have arranged the various classes in the above order, leaving simple constipation until last, since it is to the last varieties that I wish to pay the most attention. I shall now consider separately the different groups, the first ones briefly and the latter more fully.

Mechanical Constipation (Obstipation).—These are mostly surgical cases, some of the varieties rather common, others rare. I shall merely cite the causes and varieties. Gant (p. 76) mentions some 25 varieties as follows: congenital deformities and displacements of the intestines; extra-intestinal pressure; neoplasms; foreign bodies; intestinal calculi; fecal impaction; adhesions and exudate; angulation; diverticula and rectocele; abnormal mesentery; hernia, invagination, and prolapse; splanchnoptosis and enteroptosis; paralytic ileus; dilatation of the intestines; enterospasm; obstruction by intestinal parasites; hypertrophy of O'Beirne's sphincter, rectal valves, levator ani, and sphincter ani; deviated coccyx; diseases of the rectum and anus, as hemorrhoids and fissure. This class of cases embodies anatomical and organic conditions, and so I do not consider enterospasm as belonging in this group but rather under the cases due to perverted function. Nor should hemorrhoids and fissure be considered here. I shall dwell on obstipation no longer than to urge that all of these factors be taken into consideration and by a careful history and physical examination ruled out, as far as possible, before the case is treated as one of the nonobstructive constipations.

When obstipation is finally diagnosed the treatment instituted will be chosen to fit the individual case, being always, however, by removing the cause, usually by surgical means accompanied, or followed, by appropriate measures for the correction of the conditions resulting from the long continuance of the obstipation. These, in general, are diet, attention to the hygiene of the body as a whole and the bowel in particular, exercise, external and internal hydrotherapy. They will be described more in detail later on.

Chronic Constipation Caused by Diseases of Other Organs than Stomach and Intestines.—Chronic diseases of the heart, kidneys, liver, and lungs are often accompanied by varying degrees of constipation, induced by hyperemia of the intestinal mucous membrane and obstruction to the portal circulation. Correction of these conditions by appropriate means will often by itself stop the constipated state if not of too long duration. In addition to the affections of the liver, producing portal obstruction, as cirrhosis, any disorder which pathologically alters the bile in quality or quantity may produce rather obstinate constipation. Affections of the pancreas occasionally cause costiveness, but a fatty diarrhea is more common, except in diabetes mellitus where the abstraction of such large quantities of water from the body leaves the intestinal contents too dry. Various disturbances of the nervous system, either organic or functional, are accompanied by considerable costiveness, so much so that constant supervision of the inmates of asylums and sanatoria is necessary to insure against it. In these cases with the exception of the pure neuroses the laxative treatment with drugs, preferably cascara or aloes, belladonna, and strychnine pills, is indicated, combined as far as possible with diet and hygienic treatment.

Chronic Constipation Caused by Gastric Disease.—Although some of the causal factors are somewhat obscure, it is well known that certain diseases of the stomach do, *per se*, produce constipation. Those most constant in this respect are hyperchlor-

hydria, ulcer, cancer, atony, and dilatation of the stomach. Somewhat less frequent causes are chronic gastritis and achylia gastrica. Any of these may, however, produce a diarrhea or constipation alternating with diarrhea. Because of this rather intimate relationship between affections of the stomach and intestines it is wise wherever possible to take a test meal at the time of the preliminary examination before attacking the intestinal trouble.

Chronic Constipation Caused By, Causing, or Accompanying Other Intestinal Conditions.—Certain painful conditions, to wit, hemorrhoids, fissure of the anus, ulcers of the rectum, and chronic proctitis may either cause or be caused by chronic constipation, and no matter which is first in the field they are bound to aggravate each other, forming a vicious circle. The patient abstains from stool as long as possible in order to avoid the pain of a defecation, only to make matters worse when at last he has a hard constipated movement accompanied by much straining. In such a state of affairs it is necessary to reverse the ordinary method of procedure and relieve the constipation first, at least temporarily, before removing the cause. Other diseased conditions of the intestinal tract cause costiveness as one of their symptoms, irrespective of pain or voluntary abstinence from stool, as chronic catarrh of the small intestine, catarrhal or membranous colitis, and less frequently atrophy following catarrh.

Treatment is directed toward getting rid of the intestinal disorder by means of diet, irrigations, internal medication, exercise, and general hygiene. Under general hygiene we should include plenty of good air, outdoor exercise, or, if these are not possible, certain specially planned gymnastic exercises to take their place, a cold sponge bath in the morning followed by a brisk rub, proper clothing, no excess of work, physical or mental, nor undue exposure to the weather. In regard to the diet each case is more or less a law to himself, but certain general rules can be laid down. The meals should be regular, frequent, and small, and should contain no very indigestible articles. A somewhat more liberal diet may be given than in catarrhal conditions accompanied by diarrhea, but a more restricted one than is allowed in simple constipation on account of the irritated condition of the mucous membrane. The following may generally be allowed: eggs, soft-boiled or poached or omelet; chicken, fish, steak, and chops, not fried; most soups; dry or toasted bread and butter; rice, macaroni, very small amount of baked or mashed potatoes, spinach, cymlins; baked apple or pear, stewed prunes, mellow peaches; cup custard or rennet curds and whey; cream, but little milk as a rule; Postum coffee, buttermilk, matzoon, and kumyss. Small amounts at the regular meals reinforced by a toasted raw meat sandwich or a couple of crackers with a glass of buttermilk or kumyss, between meals, are indicated. Salt water irrigations or containing some medicament as ichthyol, 2 drams to the quart, or if there is much pain, extract of witchhazel, 3 ounces to the quart, are to be used, given through the colon tube, high up, with the patient lying on the left side, when the large bowel is involved. Two drugs stand out prominently for their alterative and tonic effect on the intestinal mucosa, hydrastis and ichthyol. The former is given in the form of the fluid extract and the latter prescribed in 50-per cent. solution in peppermint water, in ascending doses, beginning with about 8 drops in a wineglassful of water and increasing to 30 drops, t. i. d., provided that the stomach does not rebel. Suitable tonics may be prescribed when indicated by the general condition.

Chronic Constipation Unaccompanied by Any Organic Lesion.—We now come to the group of cases due to pathological functioning or overaction of parts of the muscular coat, and to those due to imperfect or incomplete functioning. The first of these includes the spasms of the various parts of the intestinal canal, producing spastic constipation or enterospasm. All of these do not properly come under this group, as many, if not most of them, have some anatomical cause for the spasm. Spastic constipation is not uncommon. It is produced by a spasmodic contraction of the muscular coat of a larger or smaller section of the intestine, with the result of a partial obstruction of longer or shorter duration. It forms one of the commonest symptoms of lead poisoning, may also be associated with tabes, hysteria, neurasthenia, and other nervous troubles, and according to Einhorn is at times also seen in the debilitated state following serious illness. There is often an exciting factor as an ulcer or an irritated and inflamed mucous membrane.

The treatment consists first in that of the attack and secondly in that of the underlying condition. During the attack all cold should be avoided and heat should be employed externally and in the form of enemata. Hot compresses changed every 15 minutes may relieve, but if not, a hot tub bath at 110 degrees should be tried as also a hot colon irrigation. Atropine is the drug of greatest service in relaxing spasm, and is given hypodermically in large doses—gr. 1/50 to be repeated. In one case I had to give gr. 1/20, followed by a smaller does in a half hour. Usually morphine is required in addition. The treatment between attacks resolves itself into building up the general condition and nerve tone of the patient and removing any anatomical cause which may be present.

Simple Chronic Constipation (Atony of the Bowel).—This state is usually acquired, often carelessly, and when by proper precautions it might have been prevented. Sometimes the costiveness starts in infancy, often in childhood, but it may begin at any time in life, and is very frequent in old age, when the body is on the retrograde with weak muscles and general loss of tone. The female sex are notoriously the most frequent sufferers, but not, I think, in as great proportions as compared to males as is usually estimated. Lack of exercise predisposes, as is seen in the frequent occurrence in the sedentary occupations. Invalidism and debility act the same way. Weakness of the muscles of the abdomen through overdistention and stretching, as in ascites, pregnancy, and abdominal cysts and tumors, or through fatty degeneration and infiltration in excessive obesity are factors. There are certain more active or exciting causes. One of these is neglect of regular calls to stool so that nerve sensibility is dulled and irregularity, first, and established constipation later, is the result. The individual having so long disregarded the needs of the bowel for evacuation is finally in turn treated with indifference by the bowel. A patient whom I saw, suffering at 24 years of age from a marked degree of constipation and a long train of neurasthenic and psychasthenic symptoms, confessed that when a boy he used to go as long as two weeks without a movement. Other excitants are: drug and enema habits; irregular or hasty meals; food

leaving too little a residue or the contrary, too much cellulose débris, choking the intestinal canal; too little fluids and fats; stretching and dilatation of the colon by two large enemata. That there seems to be no limit to this practice is evidenced by the case reported in the *Journal of the American Medical Association* a short time ago of an Italian who was in the habit of administering enemata to himself with a common garden hose.

Under the treatment of these cases we shall consider briefly diet, the institution of correct habits in regard to the time of going to stool, water drinking, and exercise, which are usually essential in all cases and various procedures, one or more of which may usually be employed advantageously, as irrigations, baths, massage, vibration, and electricity.

It should be insisted upon that the patient go to the closet at a certain time each day, preferably just after breakfast, whether he have the desire or not. The mind should be concentrated upon having a movement for at least five minutes, and should not be occupied by other matters as in the habit of reading at stool. If an evacuation does not result no further attempts should be made, unless there is a distinct desire, until the following day at the same time. Impress the patient with the efficacy of this, as the results of concentration of the mind are quite remarkable. To show how easily habits are formed in many cases I will relate the instance of a man I know, who used to have several movements a day. It was inconvenient, so he disregarded as far as possible all sensations coming at other times than after breakfast, with the result, in a couple of weeks, of having the desire only at that time. Later he tried, as an experiment, to see if he could produce two movements a day at will, and found on going to stool morning and evening for a week the desire came at these times.

The diet in simple chronic constipation is not rigid. Usually too much of the following should be barred: proteins leaving little residue, dry foods, eggs, thick soups. Forbid strong tea, cocoa, chocolate, huckleberries, and anything else which contains tannic acid. Plenty of the following foods, which are somewhat laxative, are to be eaten: oatmeal, cornmeal, buttermilk, cream, butter, olive oil, maple syrup, molasses, and nearly all the fruits, raw and cooked, except bananas, huckleberries, and gooseberries. As a rule it is only necessary in arranging the diet to take out the most indigestible things the patient has been eating and add the laxative fruits, oatmeal, etc., in sufficient quantities. If the patient has been gluttonous and the bowel has been dilated restrict the amount of vegetables containing cellulose. But if, as is usual, not enough food containing residue has been eaten, give a diet containing both meat and vegetables with the latter, and fruits in preponderance. Of nearly equal importance is the frequent drinking of cold water, in small amounts. For its tonic and stimulating effect a glassful should be taken every morning immediately on awakening and a half glass at intervals during the day.

Outdoor exercise when possible should be recommended. It will not only serve to improve the general condition and nerve tone, but will strengthen, among others, the muscles entering into the act of defecation. Walking or any of the mild sports are beneficial. If business or other reasons prevent this, ten or fifteen minutes morning and evening devoted to indoor physical exercise will help to take its place. When exercising the window must be open and deep breaths be taken.

A cold sponge bath in the morning followed by a brisk rub is a great stimulant. For those who can stand it a cold plunge may be substituted.

Usually all of the preceding lines of treatment are to be instituted with or without the addition of one or more of the procedures about to be mentioned. Deep abdominal massage in the morning before breakfast often does good, or the same result may be obtained by rolling a croquet ball over the course of the colon for five minutes before going to stool. Vibration by a mechanical vibrator or faradic electricity with slow interruptions are useful. Irrigations may be given of ichthyol, 1 dram to the quart, using them daily for a time and then every other day for a while longer. After a short treatment with the irrigations oil enemata of 6 ounces of olive oil, with or without a little ichthyol, may be given at night, to be retained and passed the next morning, when a movement will usually result. Or again, small cold water injections, 75° to 65°, powerfully stimulate the musculature of the intestines. It is occasionally necessary to clear the bowel out by a purge in some cases, but this should not be repeated any oftener than is absolutely necessary.

As regularity becomes established the artificial aids should gradually be discontinued, the diet and personal hygiene still being observed to make the improvement permanent. A course of several weeks or months of judicious treatment is usually followed by the most encouraging results.

PILOCARPINE.

By H. H. REDFIELD, M.D.,

CHICAGO, ILLINOIS.

PROFESSOR OF THERAPEUTICS, ILLINOIS MEDICAL COLLEGE.

Pilocarpine is one of the two chief alkaloids found in *Pilocarpus microphyllus*, or *Pilocarpus jaborandi*, Brazilian plants of the natural order of *Rutaceas*.

Jaborine, the companion alkaloid of pilocarpine, while being isomeric with it, yet in its physiological action completely antagonizes the action of pilocarpine, which fact makes the uncertainty of action when the fluid extract is used a matter of no dispute, as it merely resolves itself around which of these two antagonistic alkaloids predominates. If pilocarpine is in the ascendency, then the sweating which follows the exhibition of this agent will occur, which may in the particular instance be the effect that is desired. If, however, jaborine is the ruling principle, then an action closely allied to that of atropine will result, *i.e.* all secretions will be checked, and a result directly opposite to the one desired will be produced.

Physiological Action.—Physiologically, pilocarpine can be classed as a paralyzer of the vasomotor system, a stimulator of the nerve endings in the glands and involuntary muscle-tissue. This action, therefore, makes pilocarpine a powerful diaphoretic and sialogogue, a depressor of the cardiac muscle—by way of its stimulation of the ends of the vagus—a myotic, emetic, and under certain conditions an abortifacient. It produces profuse and rapid perspiration and salivation. The secretions of the nasal and bronchial membranes are increased, the action of the heart is primarily increased but later slowed, there is a fall in arterial tension, and the tempera-

ture is reduced from one to four degrees. The amount of urea eliminated is greatly increased, but the amount of urine is decreased, the watery constituent of the urine being eliminated through other channels. Children are affected less than adults proportionally by pilocarpine. The avenue of elimination of pilocarpine is chiefly through the skin, it being rapidly diffused, and its effects generally pass off in from three to six hours. It is said to produce contractions of the bladder and spleen.

Therapeutics.—It is the indicated remedy in ptyalism. Pilocarpine should be studied in dropsical effusions of the lung, also in renal dropsy. In cardiac dropsy, when the heart is weak, pilocarpine is decidedly contraindicated. It should be remembered in alopecia, and by some authorities it is claimed that its continued use will restore the natural color to gray hair. In eclampsia it is a remedy of sterling worth, producing quick and lasting diaphoresis and diuresis, increasing the amount of urea eliminated, and thus ridding the system of the toxins which have been the causative factors in the spasms. It should be given consideration in cases of diabetes insipidus, where it reduces the amount of urine, and by throwing the work on the skin relieves the kidneys to a very marked degree. In agalactia the exhibition of pilocarpine is productive of a profuse flow of milk. In esthenic cases of erysipelas pilocarpine is the only remedy to be given any consideration, and its action in this class of cases is so sure and prompt as to make it a specific.

LETTERS TO A NEUROLOGIST.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

VI.

Pittsburg, June 16, 1908.

Dear Doctor.—"Seek and ye shall find"—when I awoke this morning these words were uppermost in my thoughts. I reflected: since my prayers have so far been of no avail, and since I believe that there is Divinity in all things, perhaps it is human aid I should seek. I am told that you have insight and judgment, and although I do not know you, I have determined to lay my troubles before you. After you have heard my story, I shall be glad to have a personal interview with you if you deem it advisable. In the difficult and delicate matter which I have to put before you, I shall be as frank as possible and endeavor to do no one an injustice.

My only son is an habitual drunkard. He goes for weeks, even sometimes for months, without drinking a drop, but during this period of abstention he is pale, depressed, ambitionless, absolutely indifferent and silent, even towards me whom he loves. At the end of a more or less extended period he begins to drink, a little at first, then increasingly, until there is but one thing left for him on earth—alcohol. He does not eat, does not sleep, does not come back to our house until he is brought there, a wreck in body and mind. Then begins the slow creeping back to health, and with it remorse and indications of self-disgust. His stomach for a long time refuses food, but after a week or so of strict dieting he begins again to be as he was before the drinking bout began. Physicians say that his health is greatly undermined, and that he cannot survive his way of life for many years—and he is the only thing that makes life worth living for me.

I married at nineteen a prosperous, pleasure-loving, narrow-minded young man. His desires and caprices, whatever they may have been, have always been proportionate to his ability to gratify them. He has been what is called successful, and, although too self-centered and selfish to be really popular, his *lack of insight* has prevented him from appreciating the world's attitude towards him. He is thoroughly self-satisfied.

All our younger children died in early infancy. Our son, George, is now thirty-five years old. He has been the sunshine of my life, but there has always been something lacking in his father's appreciation of him. This failure to understand his son perhaps accounts for the lack of sympathy between them. In childhood and later, when he was grown, George displayed great facility up to a certain point in anything he undertook. In school and in college he stood fairly well in his class, never first, but his position was gained without effort. He had facility in dancing, swimming, tennis, sports of all kinds, but as soon as a certain proficiency had been gained he lost interest and allowed his associates, less highly endowed by nature, to surpass him at every point. On leaving college his father was unwilling to have him join any club, and it was then, I believe, that he began to frequent hotels and their bar rooms. I noticed that he was frequently under the influence of liquor, and I recall that during his college days, which were passed away from New York, and also during the vacations, I occasionally saw him slightly excited by alcohol. He wished his father to give him sufficient money to start in business or to buy a seat in the Stock Exchange, but whether his father had small confidence in his business ability, whether he preferred to keep the reins in his own hands, or whether it was simply that he was too selfish to reduce his own income, he refused to gratify his son's wish, but took him into his own office instead, where he was not particularly needed, and where he felt of little importance.

It was soon after this that I observed signs of discontent in my son, a growing lack of ambition, and an increasing fondness for alcohol. When he indulged in moderation, he became the most charming and delightful of companions—witty, sympathetic, lovable, and interested in everything. He began to be much sought after by society, and I cherished the hope that he would fall in love with some woman who "should be good for everything at home," but, as far as I can learn, he has never seriously cared for any woman.

On account of the increasing lack of sympathy between George and his father, I felt that if I added criticisms and admonitions to my husband's cold disapproval, my child's home would soon become a place for him to avoid. For this reason and because criticism made him irritable I refrained from reproving him. Of late my son has been indulging in self-pity, and is trying to place the responsibility of his failure on his father. He says to himself, "Had I been able to marry, to have a home of my own, all would have been different!" My husband resents this attitude, and at times they are scarcely on speaking terms. In my despair I have spoken to one or two of George's intimate friends, and they seem to feel that he has not been fairly treated by his father.

But is it possible for one generation to be just to another? I, naturally, am inclined to sympathize with George in all things—I weep over his wasted youth, and yet a sense of fairness makes me stop to consider if any individual is really responsible for the actions of any other, whether our real foes, the ones we have to meet in deadly conflict, are not within us, are not our own weaknesses and deficiencies; whether, when we fail, it is not because our weakness is greater than our strength, and whether we are not in reality beaten before we begin the battle of life. In moments of depression I reflect that if we are not climbing the hill, we are all rushing down as fast as we can.

You realize, no doubt, how unfit I am to counsel my son. And even though I advise him in a way which might meet the approval of an impartial judge, when it is contrary to his likings he cannot be made to appreciate that my counsel is not somewhat prejudiced. He fancies that the world, like his own family, has failed to give him a square deal. I see in some of his actions an expression of resentment against this fancied wrong. Indeed, it seems to me that at the present time he lacks not only the necessary motive, but the ability to help himself. He has failed the bright promise of his early day, but I know he has qualities and capacities which, if they can be developed and fostered by guidance and wise counsel, will make for the happiness and welfare of others besides himself.

I hope I have adequately conveyed to you my belief that in times past he has tried to help himself, but in ways which seem to me wholly inadequate, and which have proven so. I mean by "swearing off" or resolving not to drink until a certain day, by promising me to abstain, etc. I feel that no definite plan of action has ever been taken with him, that he has never been apprised of the philosophy of a cure.

Is there any help for him? My own griefs, disappointments, failures, which I shall not enumerate, have crushed my spirit, and in my despair I snatch at the ray of hope which my knowledge of your ability offers me.

Dear Madam.—While thinking over the contents of your letter, my memory invoked a passage which serves as the introduction of a book, nowadays little read, but which delighted many hours of my youth. It seems to me to have peculiar application to you in your present predicament. "They who listen with credulity to the whispers of fancy, and pursue with eagerness the phantoms of hope; who expect that age will perform the promise of youth and that the deficiencies of the present day will be supplied by the morrow, listen to the story of Rasselas." I am afraid you have listened to the whispers of fancy and pursued the phantoms of hope, and that you believe the morrow will supply what is lacking to-day. Such mental attitude is the basis of much happiness and the warp and woof of optimism.

I desire sincerely to help you, but all that I can do is to counsel you to a plan of action which, put into successful operation, will constitute a *modus vivendi* for you, your boy, and his father. You want at the same time to break him of the drink habit and to restore the proper relationship between him and his father. It will be easier to accomplish the former than the latter. Although you say very little about his father in your letter, I gather from what you do say that his extreme self-satisfaction would prevent him from critically examining his own attitude towards his son and making allowance for infirmities which he does not possess. Nor is he capable, I fancy, of appreciating that inhibition is a quality which men possess in varying degrees, and that in proportion to its possession is their capacity to resist temptation. A man may be proud of his birthright, but he does not boast of it; rather is he moved to give encouragement and a helping hand to those who are less fortunate. Virtues which fail to make us more tolerant of the infirmities of others are like riches to them who have no desires—burdensome. Moreover, your husband has had for a long time the attitude of being in the right and of brooking no argument undertaken to convince him of error. Therefore, I am not encouraged to believe that much can be done with him or through him. Whatever is to be accomplished has to be done through the young man himself. The first thing to develop in him is *amour propre*. He must be made to see and to appreciate that by persistent indulgence in this habit he is outraging his birthright and debasing himself in the eyes of his fellow-creatures, and killing one by one all those qualities which distinguish him from the brute. Moreover, he must be apprised of the fact that a continuance of his present mode of life will inevitably entail infirmity of body or of mind, which is bound to be productive of great suffering, and that no amount of pleasure makes up for a comparatively small amount of pain.

To put this in an entirely different way: Suppose you ask your son what is the object and purpose of life for him, do you think he will be able to define it or to give you any formulated expression of what his ideas upon this matter are? Have his conduct and mode of life heretofore betrayed any sentient purposefulness other than to amuse himself or to facilitate the rapidity with which one hour succeeds another? It is to be presumed that every one has an aim or object in life, even though few of us are able to describe it intelligently. *The object in life is to do the work of the hour or of the day.* Take a young man such as your son, who has reached a period of life when it is proper seriously to question the objects and aims of life, its duties and privileges, he should have studied the map of life and planned out a campaign with the studiousness and care that a general gives to the country and the forces by whose aid he hopes to win his decisive battles. "Into this Universe, and why not knowing, nor whence, and out of it he knows not whither," but while he is here he has a duty to himself, his family, the public, to society, and to posterity.

By what is his conduct mainly determined—I mean his whole conduct? He prefers to act in a way which will be productive of temporary pleasure rather than in a way which will conform to what the world, or convention, calls right. What incentive therefore exists or may be called into existence which will lead him to exchange a mode of life that pleases him and disheartens you, for one that he believes is comparatively devoid of pleasure, though it would realize your fondest hopes? The disadvantage of having the kind of a father which you describe your son as having is twofold; first, he fails in his duty, which is to develop in the child the best traits and qualities and to teach him to control the least desirable ones, and second, by his very lack of sympathy and under-

standing, he often drives the mother into too soft and indulgent an attitude.

Your boy seems to have had unusual endowments. In early life, his ambition should have been stimulated, his career as an individual planned, and he should have been made to feel the dignity and responsibility of his own life. Byron says, "Man is a reasoning animal, therefore he drinks!" If your son had been a degenerate or a dipsomaniac, it would have been another thing, but in his case the fact that he took to drink does not contradict his ability or promise, it only shows how little adequate motive or necessary ambition he had to get the best out of himself.

Before we outline a plan of conduct or course of life which we shall advise your son to follow, assuring him that if he does so he will cast his fetters, and that the joy of life will be enormously increased, we must try to put ourselves in his place. If we attempt to convince him by argumentation that he should give up taking strong drink, he is apt to ask, "To what purpose?" or, "Why should I?" What rejoinder shall we make? We may say that he will injure his health, curtail his life, humiliate his family, outrage society, and possibly even menace public decency, but none of these save the third will probably make an appeal to him. So far he has not interwoven his life very closely with the lives of others and he has failed to become the center of a new community. He is not likely to do so now that he has reached the beginning of the second half of life. Society, he will tell you, demands of him that which he gives willingly, and no more. What, therefore, are his social bonds? To so conform his conduct that it does not bring him into contact with the laws of the country, and to be as popular as it is possible to be without fatiguing effort. If you attempt to discuss with him those relationships with persons whom he does not know, whom he knows only very casually, and those who do not materially enter his life, which, with our friends, constitute our life's history, what will he say to you? He will probably say that they do not concern him and that he gives no thought whatsoever to them. You will find it difficult, I think, to arouse an interest in him which will tend to the advantage of the community. A man who approaches his fortieth year without having shown some inclination toward municipal, religious, ethical, political, or other public work is not apt to take it up at that age. Neither does such a person develop a hobby, the pursuit of which, for many of us, contributes so much to the pleasures of life. As a matter of fact, if you were taken from him, your son would be an extremely isolated person; indeed, I think the sense of isolation, which is mainly due to his father's limitations, has had something to do with the development of the drink habit.

We may aid to break the drink habit in a number of ways, but in no other direct way than by providing him with a motive. This motive may be developed (1) through hypnotism, which is a somewhat doubtful expedient, especially in cases of this kind, where there is a lack of character rather than an abnormality or perversion; (2) through religious conviction, bringing about what is popularly called a conversion; (3) through a desire to please and to be worthy. A motive may develop in association with some person with whom he may be fortunate enough to fall in love. This is a strong enough motive to induce change of conduct in some persons, the motive in such cases being to win the love and respect of the other person, the consideration offered in return being cessation of a mode of life that the loved one believes to be degrading; in short, the desire to please; (4) through the friendship of some man or woman whose personality would have a marked influence upon him. George Eliot, in touching upon this in Daniel Deronda, says: "It is one of the secrets in that change of mental poise which has been fitly named conversion, that to many among us neither heaven nor earth has any revelation till some personality touches theirs with a peculiar influence, subduing them into receptiveness." (5) By means of a weaker group of motives, which might be called the social, or philanthropic motives. It is conceivable that this young man might have sufficient social instincts and love of his fellowman to cause him to engage in some line of work which would make for social progress. One might get him interested in some special problem, like tenement-house reform or playgrounds for children. A person who is himself intensely interested in some such subject could talk to him about it and try to gain his interest in much the same way as if he were trying to make a sale or induce him to insure his life.

I am assuming that you are not willing to adopt the drastic measure of putting into operation what is, after all, the most forceful motive, namely, the earning of a livelihood. If, for example, you had known when your son was in college what the future had in store for him and how his character would develop, my advice would have been, make him understand that after he has graduated from college, every source of income from the family will be absolutely cut off. Often this fails to work very well because children, especially in this country, are imbued with the idea that they have a natural right to the monies which their fathers have amassed, and cutting off the supply from the young man abruptly, especially when he has reached the age that this young man has attained, is apt to fill him with such resentment that he will go to the dogs out of spite.

Transoceanic Emigration for 1908.—P. Rosati gives statistics for the emigration from Italy in the year 1908. He shows that the emigrants come to the ports from country district, with carelessness of hygiene, crowding, and poor food. The trains move very slowly, and men, women and children are crowded into old and dirty cars with their luggage. He remarks the repugnance of the Italian peasant to the use of water, and says that it is impossible to get him to use it before he goes upon the steamship, where he is again restricted to small quarters. Trachoma is very frequent, and he states that in most neglected cases it ends in blindness. Skin diseases of parasitic type are naturally frequent among them. Contagious diseases of childhood, and tuberculosis, are also present. The food that they can obtain from the railroad eating houses is of poor quality, and, combined with the lack of hygiene and of toilet facilities along the route, leave many of the emigrants in poor condition before they begin their voyage. When they return from a voyage to South America they bring with them the diseases of tropical countries, ankylostomiasis being frequent, as well as malaria. Many consumptives also come home to die. Trachoma is largely caused by dirt and ignorance, and education in this matter is most important, especially in cleanliness. There is need of small pavilions, where these diseases can be cared for and isolated, with simple surroundings such as these people are used to, but with good hygiene and sanitation. Large and costly buildings would be out of place; good medical treatment is a necessity. When the law providing for better quarters for emigrants on the steamers was first put into effect the resistance on the part of the steamship companies and other interests to its enforcement was very great. Now this is changed, and some of those who resisted most at first are now most anxious to carry it out.—*Annali di Medicina Navale e Coloniale.*

New York, March 12, 1910.

THE ROLE OF LACTALBUMIN IN MILK DIGESTION.

SINCE in the year 1884 Biedert published the account of his studies demonstrating that there was a distinct difference, not only between the percentages, but also between the intrinsic characteristics of the casein of woman's and cow's milk, the study of the various proteins of the different milks has been the most important object of research among those interested in the feeding and care of infants. The first great step in advance in this work was made by Sebelien when he showed that milk contained two kinds of protein, casein and lactalbumin, and that in woman's milk the proportion of the latter was much greater than in cow's milk. Since then many theories have been advanced as to the fate of these two substances in the infant's stomach, and their effect upon the digestibility and assimilability of the milk, the main conclusions of which have been that the advantage of woman's milk over cow's milk lies in the fact that lactalbumin is a more easily digested substance than casein, and that the woman's milk contains an excess of this favorable form of infant food. In the *Berliner klinische Wöchenschrift* for January 3, 1910, Bickel and Roeder have published the results of some researches which tend to show that the function of the lactalbumin may be more important than this, that it not only is easily digested itself, but that its presence may also in some ways exert a beneficial effect upon the digestion of casein as well.

The first experiment was a simple study of feeding and weighing. Eight puppies of one litter were allowed to suckle their mother. To two, which were used as controls, nothing else was given; to three was administered daily a definite amount of a soluble salt of lactalbumin; to the other three was given an equal amount of casein. The puppies receiving the albumin in addition to their mother's milk gained in weight distinctly more rapidly than did the control dogs, while those receiving the casein were as uniformly slow in growth. These relative ratios were also maintained when the maternal milk was replaced by cow's milk in the six pups receiving the test food, the controls in the meantime continuing to nurse. The cow's milk with the addition of the lactalbumin seemed to nourish the animal even better than the food which nature had supplied for it.

The second series of investigations was undertaken to study the effect of lactalbumin upon gastric motility. A dog, in which a duodenal fistula had been made, was fed various solutions, and by extracting small quantities of the intestinal contents every two minutes, not only was the condition of the food studied after it had been acted upon by the gastric juice, but the time which it remained in the stomach was ascertained as well. On two occasions, when solutions consisting of 35 c.c. of cow's milk, 65 c.c. of water, and 4.0 grams of milk sugar were given, eighty and ninety minutes respectively elapsed before the stomach had completely emptied itself. On the other hand when plain water, woman's milk, or a similar cow's milk solution, differing only in the addition of 0.5 gram of lactalbumin were fed, the last traces had passed the pylorus in from fifty-six to sixty-two minutes. Even more suggestive than this, however, was the fact that, whereas the plain milk solution upon reaching the duodenum was in coarse, firm curds, the solution containing the lactalbumin was in the form of the fine flocculent particles characteristic of partly digested woman's milk; in fact, the two being placed side by side could not be distinguished from each other. Taking their cue from these experimental findings, the authors proceeded to feed a small number of seriously ill infants, who were unable to take the ordinary milk modifications, with solutions of cow's milk containing in addition 0.5 gram of the salt of lactalbumin to a feeding. The results were most strikingly satisfactory.

The number of these experiments and of the cases treated is far too small to warrant their being used as a basis for any conclusions. The results are, however, decidedly suggestive, and if it is a fact that the usefulness of lactalbumin is deeper than that merely of an easily digested protein, and that its presence in the stomach is the real reason for the difference between the clotting properties of cow's and woman's milk, the fact should be proved by further investigations and a satisfactory explanation of the phenomenon offered. If further work confirms the accuracy of the present contribution, it may prove to be an addition to the science of infant feeding of no small value.

THE RESULTS OF VACCINATION.

TRITE as the subject of vaccination may seem it is one over which there is as much controversy among the general public as there is about anti-vivisection or the suffrage. While it may seem established beyond a doubt that vaccination protects against smallpox, and while we have only to compare the ravages of this disease as it occurs to-day in countries in which vaccination is not practised with the immunity which we enjoy in a country where vaccination is general, still any physician who comes in contact with the parent of the school-child realizes that we are far from reaching unanimity as to the value of this practice. It is an everyday occurrence in a public school to have parents deny the value of vaccination, dilate on the deaths that it has caused by tetanus and sepsis, question its protective value, and deny the right of the majority of the

community to require its performance as a matter of protection. We are told that many physicians do not believe in it, but declare that it is not only useless but injurious. We are also told that a child should not be vaccinated in cold weather lest it should take cold in the sore. We are met with an absolute refusal to allow vaccination before admission to a public school, and an unwillingness on the part of the Board of Education to force the matter on a taxpayer, lest a suit should bring out the inability to enforce compulsory vaccination. It seems high time that the public should be further educated in this matter, should know the history of vaccination in those countries of Europe in which it has shut out smallpox, and of the high death rate among children, and the thousands of cases of blindness due to variolous ulceration of the cornea, which are to be found in China and Corea.

The matter is brought up anew by the statistics of Goldschmidt of Strasburg, in the *Revue de Médecine*, for September, 1909, in which he gives the results of vaccinations practised since 1872 on many thousands of children. Primary vaccination was practised from arm to arm from 1873 to 1883, with the result of 94.37 per cent. of successful "takes." From 1885 to 1895 the author made use of glycerinated pulp. From 1885 to 1895, 3,312 primary vaccinations gave 98.88 per cent. of successful results. But in both these groups there were six scarifications made in each case, three on each arm. We meet with these cases in examining school children, with each arm scarred with three cicatrices, a severe disfigurement for a girl in this age of short sleeves. Yet our author claims that this method gives a much larger percentage of successes than when fewer scarifications are made. While we have no statistics to offer, we feel sure that it is the experience of those performing public vaccination, that it is possible to get almost 100 per cent. of successes with glycerinated vaccine when perfectly fresh, with a single scarification. Yet one frequently meets with cases in which vaccination has been practised from two to six times without success; albeit every one of them has been found to take when vaccinated with fresh glycerinated vaccine. There is certainly a misconception among physicians of the frequency of immunity against vaccination. This misconception has arisen from the use of inactive vaccine, and Goldschmidt gives us the reasons why so many specimens of vaccine are absolutely inert. Vaccine pulp, according to him, if kept in contact with glycerin for more than two weeks loses a great measure of its activity. Again, if diluted with too much glycerin it becomes so attenuated that it loses its efficiency. A third reason is that its efficiency lessens as it is kept, the same specimen showing good results when first used, and progressively less efficiency as the days go by.

To those who vaccinate large numbers of children and have the opportunity of observing these vaccinations from week to week, as they go through the process of evolution, these facts are well known; but by those who vaccinate only occasionally and do not watch the results, they seem to be unrecognized, and these are the physicians who certify that their patients show a natural immunity against vaccination, and are supposedly immune also to smallpox. The fallacy of this belief is shown by the results of any epidemic of this disease. Goldschmidt cites an epidemic occurring in Alsace-Lorraine after a period in which vaccination had been practised with ineffective virus. The epidemic could not be stayed until the inhabitants had all been vaccinated and revaccinated with fresh, active vaccine. In the epidemic of smallpox in this city some years ago, in which New York furnished 600 victims, it was noticeable that the cases reported daily to the Health Department were all either in babies under five years of age, who had never been vaccinated, or in persons over school age who had neglected revaccination. Not a case in a school child appeared on the lists. The value of the vaccination of school children is here shown. It would seem that valuable statistical studies could be made in this city and published, so that every physician may read them, and every citizen be informed of them, and that so the antivaccinationist may be silenced, as the equally uninstructed antivivisectionist will be, before legislation is passed which shall retard the progress of medical science in this State.

VENEREAL DISEASES IN THE ARMY.

It has ever been one of the most difficult problems with which army surgeons have to deal to know how in the most effective manner to cope with venereal disease in its various forms among the rank and file of the forces. That it cannot be abolished outright is a fact which must be at once faced, in spite of the maunderings of sentimentalists, both male and female. These well-meaning individuals, as a rule, do not like to hear a spade called a spade, but prefer to close their ears to plain talk on the subject, and what is worse, frequently hamper the efforts of those who have been taught, by experience, the best means of fighting the evil. By the endeavors of persons of this class the attempt to prevent venereal disease in the British Indian army was thwarted, but as Kipling might say, "that is another story." Suffice it to say, that so far as the American army is concerned, venereal disease is so prevalent as to be a direct menace to its effectiveness as a fighting force.

Lieutenant-Colonel Henry T. Raymond, Medical Corps, U. S. Army, writing on the matter in the *Military Surgeon* for December, 1909, lays down the following postulates: 1. Specific urethritis is the cause of more misery, invalidism, and noneffectiveness in the army than in any other disease. 2. Soldiers will expose themselves to venereal infection as long as human nature remains unsanctified. 3. Moral suasion alone is inadequate to effect the desired revolution. 4. To effect escape from the physical ills of a sinful practice is a legitimate end of sanitary endeavor. It is not "encouraging vice." The young man who avoids promiscuous intercourse from principle will not be misled through proffered immunity from infection. 5. A rational method of prophylaxis or prevention of specific urethritis has been devised, its general adoption in the army requiring the enactment and

enforcement of a new military regulation making the contracting of a specific urethritis a military offence.

The foregoing postulates are laid down by a man who thoroughly knows his subject, and, therefore, any measures suggested by him as calculated to improve conditions may be pondered with advantage. Colonel Raymond, in 1905, introduced what he termed the "K" package as a preventive of infection. This package consists of a dram vial of a solution of one of the organic salts of silver, and a medicine dropper, wrapped in a small packet for the vest pocket. The soldier is notified of the existence and purpose of the package, by a notice posted in the company lavatory, while each individual member of the command is given a circular on the A B C of venereal diseases. This A B C is arranged in the form of questions and answers and sets forth in plain and concise language the salient features of gonorrhea, syphilis, and chancroid and the necessity for employing preventive measures to avoid infection.

The results of Colonel Raymond's methods have been most satisfactory. He urges that the contraction of specific urethritis by the soldier should be made a military offence, on the grounds that the use of the "K" package if employed intelligently and in time will surely prevent infection, and that the contraction of infection is an argument in favor of negligence if not untruthfulness. There would seem to be no valid reason why the American soldier should be more subject to venereal infection than is his European brother in arms. Probably one cause is that he is given more freedom than the old country soldier. However, when freedom degenerates into license to the detriment of the service, vigorous efforts must be made to assert discipline.

The Prevention of Typhoid Fever.

The prevalence of typhoid fever almost everywhere in this country is a national disgrace. That it does occur far more frequently on this Continent than it should is so evident as to call for no proof. The fact that the average typhoid death rate in the United States was, according to the census of 1900, 46.5 per 100,000, while that of England and Wales was but 11.2, is an incontrovertible proof of the undue prevalence of the disease here. At the annual meeting of the municipal health officers of Ohio, held at Columbus, Ohio, January 20-21, 1910, L. L. Lumsden, Passed Assistant Surgeon, U. S. Public Health and Marine Hospital Service, read a paper on what the local health officer can do in the prevention of typhoid fever, and it would be well did the local health officers everywhere take his recommendations to heart. He said that the health officer should first of all become informed as to the best-known means of prevention, the proper care of the excreta from sick persons, and proper general sewage disposal. He should also secure the prompt report of recognized cases and of suspected cases, so that preventive measures may be begun early. Dr. Lumsden thinks that the early report of cases and suspected cases should be made a legal requirement if possible. The health officer should advise and have carried out at the patient's bedside efficient methods of prevention. The health officer should be legally empowered to have bedside measures of prevention properly carried out, but even if he is not so empowered he can accomplish a great deal by the use of moral suasion on the family and the attending physician. He should have preventive measures continued as long as the dejecta are infective. Probably considerably more than 3 per cent. of persons recovered from typhoid fever continue to discharge typhoid bacilli for two or three weeks after convalescence is established. On general principles, the use of disinfectants in the stools and urine of typhoid convalescents should be continued for at least two weeks after defervescence, and, whenever practicable, bacteriological examinations of the dejecta should be made and the convalescent should not be discharged from the supervision of the health officer until at least two such examinations have given negative results for the typhoid bacillus. Bacillus carriers should be discovered and the spread of infection from them should be safeguarded against. Proper disposal of the sewage should be secured. It would be superfluous to enumerate here the various modes in which infection can be spread if the sewage be not disposed of properly. This is really the most important means of prevention. Dr. Lumsden insists that in communities unprovided with good water-carriage sewerage systems, health officers should strive unceasingly to secure the adoption of safe methods of sewage disposal, and if the pail system or the dry-earth closet system has to be used, a model privy should be kept on exhibition at the health office. Typhoid fever is a disease in which preventive measures count far more than curative. If effective preventive methods be not put into play as soon as possible, the spread of the disease is more or less certain and an epidemic may ensue. Perhaps, Dr. Lumsden has placed on the shoulders of health officers somewhat more than the majority will be able to carry, but his arguments are in the main eminently rational.

The Differentiation of Exudates and Transudates.

Each year the use of the exploratory needle for the diagnosis of collections of fluid in the human body is becoming more general, as by it not only may the presence of the effusion be confirmed, but in most instances its character and the nature of the underlying process may be determined. Pus or blood in one of the serous cavities is easily recognized by a mere glance at the aspirated material, and the finding of either usually gives both the diagnosis and the indication for treatment. When the puncture fluid is clear, however, the problem is more difficult, as the question arises as to whether the process is one of transudation due to stasis, or of exudation from inflammation. In deciding this much may be determined by a careful analysis of the fluid in a laboratory. The estimation of the albumin content, the specific gravity, the differential count of the contained cells, the freezing point, and the viscosity all give valuable information in the hands of a skillful laboratory worker. The practising physician, however, having neither the time nor the technical skill to carry them out is practically debarred from using these procedures. There is one method of examining such fluids which is simple and rapid, requires no especial training, and is considered of sufficient accuracy for clinical purposes, namely the occurrence or ab-

sence of a precipitate when the fluid is treated with dilute acetic acid. This phenomenon, though not new, is not sufficiently well known among the profession at large and an article by Pieper in the *Münchener medizinische Wöchenschrift* for January 4, 1910, upon the subject is thoroughly acceptable. According to the author the chemistry of the reaction is still undecided, and it need not be considered here. The practical test may be carried out by either one of two methods. Moritz recommended adding one or two drops of a five per cent. solution of acetic acid to two cubic centimeters of the fluid to be tested, whereas Rivalta allowed one or two drops of the puncture fluid to fall into a cylinder containing two drops of glacial acetic acid in one hundred cubic centimeters of water. By the first method an exudative fluid at once forms a more or less thick cloudiness or even a heavy white precipitate. By Rivalta's method, as the drop sinks it is followed by a streak in the fluid closely resembling a wisp of cigarette smoke. If the fluid being examined is a transudate these phenomena do not occur, or at most there is formed but a slight pearly opalescence. The test tubes should be observed in front of a black background. The author has examined 130 specimens from various sources and finds that the Moritz test is absolutely reliable in fluids from all serous cavities; where in a few cases of definite ascitic transudates the reaction was positive, the autopsy later demonstrated the existence of secondary infections. Rivalta's method has the advantage that but one or two drops of the suspected fluid is required. It is, however, though equally accurate in all other forms of effusion, somewhat indefinite when applied to cerebrospinal fluid. A thorough understanding of the two methods and their intelligent use may well be of value to the clinician in determining the often puzzling question of the differentiation of exudates and transudates.

Medical Inspection of Juvenile Criminals.

Perhaps the greatest advance in recent years in the criminology of the young has been made by the establishment, in many of the large cities, of the children's courts, by means of which the youthful offenders not only are kept apart from the older and more confirmed criminals, but also are brought in intimate contact with justices and with charitably inclined persons who have made especial studies of child psychology, whose influence, properly exercised, has done much to rescue many children and youths who have taken their first step in the paths of crime. That those who are interested in this movement are not content with what they have already done, but are anxious to continue and broaden their work and to place their movement on an even better and more scientific basis, is shown by the report recently submitted to the Mayor of New York City by the secretary of Division I of the Children's Court, over which Mr. Justice Deuel presides. In this report it is suggested that a hospital be founded in connection with the court to which all children who come to the court may be referred; there they will be thoroughly studied by competent physicians in order to determine to what extent the moral laxity may be due to physical defects, and wherever possible to correct such bodily ailments as may be discovered. The report says in part: "It has long been known scientifically that many adult criminals are victims of conditions, acquired or hereditary, which result in a mental disturbance predisposing them to the development of criminal tendencies. With such cases the time for relief, if curative or meliorating remedies are possible, is in youth, and at the first indication of criminal tendencies, and the best opportunity, therefore, is through the Children's Court, whereto such unfortunates will naturally drift. It can thus be early determined with suitable medical expert assistance whether the difficulty is curable or incurable. Cures will be less expensive to the public than confinement in charitable institutions and later on in reformatories, prisons, and workhouses. The ascertainment of incurability will be of value when youth ripens into full maturity. There are also cases of feeble minds that come through similar causes and are susceptible of help sufficiently to stop the criminal inclination. The court has been experimenting somewhat in this direction and has the subject under most careful consideration. It lacks proper facilities for determining the value of such work. There is no institution to which such children ordinarily may be committed that possesses such facilities in any proper degree." The establishment of such an institution would certainly seem to be a step in the right direction, and it is earnestly to be hoped that the proposition will be crowned with the success which the enthusiasm of its promulgators so richly deserves.

News of the Week.

A Child Welfare Exhibition is to be held at the Seventy-first Regiment Armory in New York City during the month of November, 1910. The projectors of the exhibition purpose to make it even more vivid and pictorial than the Tenement House Exhibit or the recent Tuberculosis Exhibit. To show the facts of child life as they exist in this city, model houses and flats, moving pictures, panoramas, and photographs will be employed. Where statistics are used they will be presented objectively as largely as possible. The entire center of the armory floor space will be kept clear, so that exhibitions can be given of dances, pageants, gymnastic drills, and model play exercises.

The Metropolitan Sewerage Commission, first constituted in 1906 and in 1908 continued until May 1, 1910, is ready with its preliminary report upon the best method of disposing of sewage in New York Harbor. The most important conclusions reached by the Commission are that it is not possible to protect the waters of New York Bay and vicinity by intercity agreement. There are about eighty municipalities concerned, and the subject would be beyond their capacity to regulate properly. It is desirable to establish a sewerage district in order properly to dispose of the wastes, and the Commission believes that this would be the best way in which the sanitary condition of the harbor could be conserved. The most desirable limits for the sewerage district would include a territory of about seven hundred square miles, about half of which would be in New York and half in New Jersey. The best system of administrative control would be an interstate commission, but a separate and distinct sewerage district and a permanent commission in each State would be an effective instrument toward the accomplishment of the end desired, and it would probably be more feasible at this time to create two separate commissions than

a single metropolitan commission having jurisdiction over both States. If two commissions could be so formed as to act in harmony the effect would be nearly that of one interstate commission.

The von Recklinghausen Testimonial.—National committees have been formed to receive contributions from the friends and former students of Prof. F. von Recklinghausen, who three years ago retired from the professorship of pathological anatomy which he had held with distinguished success for thirty-five years in Strassburg, where he is still working with undiminished energy and industry in completing investigations begun over ten years ago. In conformity with his known preference the funds contributed are to be used for a "von Recklinghausen Foundation" for educational and scientific purposes, but the determination of the precise terms and uses of the foundation is to be left to Prof. von Recklinghausen. The opportunity is given to his American friends, admirers, and students, who desire thus to honor this great teacher and master of pathological anatomy, to send their names and contributions either to one of the undersigned members of the American Committee, or to the "Aktiengesellschaft für Boden und Kommunalkredit" in Strassburg, i. Els., Germany. The receipt of contributions, which will close on May 1, will be duly acknowledged. J. George Adami, Montreal; Willard Bartlett, St. Louis; F. Forchheimer, Cincinnati; G. Fütterer, Chicago; A. Jacobi, New York; W. Ophüls, San Francisco; B. Sachs, New York; James Tyson, Philadelphia; W. H. Welch, Baltimore; Francis H. Williams, Boston.

Vaccination Statistics in Great Britain.—That Great Britain is yearly laying itself more open to the dangers of a great smallpox epidemic is evidenced by the rapid growth of the objection to vaccination in Great Britain as shown by the latest statistics. In the year 1906, 935,338 births were registered and the certificates of declarations of conscientious objections to vaccination numbered 52,391, or 5.6 per cent. In 1907 the certificates of objection amounted to 6.2 per cent. of the births and in 1908 to 17.2 per cent. In the first six months of last year, 1909, they reached 18 per cent. The percentage of unvaccinated children yearly is even greater than these figures show, as the statistics quoted refer only to those who have not been vaccinated because of conscientious objections on the part of their parents.

The Third International Laryngo-Rhinological Congress will be held in Berlin during August or September, 1911. Inquiries regarding the Congress to be addressed to the Secretary of the Executive Committee, Prof. Rosenberg, 26 Schiffbauerdamm, Berlin N.W. 6, or to Dr. Finder, 17 Nettelbeckstr, Berlin W. 62, Secretary to the International Committee.

The Third International Congress of Physiotherapy will be held in Paris, March 29 to April 2, 1910, under the presidency of Prof. L. Laudouzy. A detailed program of the work of the Congress and other information may be obtained from the Secretary-General M. le Dr. Vaquez, 27 rue du Général-Foy, Paris.

Reception Hospital for the Insane in Providence.—The Board of State Charities and Corrections of Rhode Island has voted to erect a new reception hospital at the State Hospital for the Insane. The purpose of this addition is to give patients who may be curable the opportunity to be treated without being brought into daily touch with patients who are hopelessly insane.

"The American Journal of Physiological Therapeutics" is to be published shortly in Chicago. The journal is to appear bi-monthly and will be devoted to such subjects as hydrotherapy, electrotherapy, massage, and hyperemia.

Dr. Charles F. Peckham of Providence has been elected Surgeon-General of the Rhode Island National Guard, succeeding Dr. George H. Kenyon, resigned.

Dr. Frederic Bierhoff of New York has removed to "The Pasadena," 10 West Sixty-first street.

Charitable Bequest.—By the will of the late Annie Leidy of Philadelphia the sum of $1,000 is bequeathed to the Charity Hospital of Norristown. By the will of the late Lewis Conrad of Philadelphia the sum of $100 is bequeathed to the Children's Homeopathic Hospital and $50 to the Friends' Asylum for the Insane at Frankford.

The Council of Physicians and Surgeons of New Brunswick held its annual meeting at Fredericton, N. B., on February 22, 1910. The election of officers resulted as follows: *President,* Dr. J. H. Gray of Fairville; *Treasurer,* Dr. Thomas Walker of St. John; *Registrar,* Dr. Stewart Skinner of St. John.

The Tri-County Medical Society was organized at a meeting held at Ellsworth, Kan., on February 18, 1910. The society will be composed of physicians from the Counties of Ellis, Russell, and Ellsworth. The following officers were elected: *President,* Dr. H. Z. Hissem of Ellsworth; *Vice-President,* Dr. J. W. Catudal of Hays City; *Secretary,* Dr. A. E. O'Donnell of Wilson; *Treasurer* Dr. C. D. Blake of Ellis.

The Medical Association of Sagadohoc County (Me.) held its annual meeting at Bath on February 23, 1910, and elected the following officers: *President,* Dr. B. F. Barker; *Vice-President,* Dr. I. C. Irish; *Secretary,* Dr. R. C. Hannigan; *Treasurer,* Dr. L. T. Snipe.

The Waterville (Me.) Clinical Society held its annual meeting recently and elected the following officers: *President,* Dr. A. A. Downs of Fairfield; *Vice-President,* Dr. H. E. Milliken; *Secretary and Treasurer,* Dr. Edson E. Goodrich.

Obituary Notes.—Dr. Ezekiel W. Cooper of Camden, Del., died at his home on February 22, 1910, aged 75 years. Dr. Cooper was a graduate of the University of Pennsylvania in 1861 and was a member of the Kent County Medical Society and the Delaware State Medical Society. He was for several years President of the Delaware State Board of Health and a member of the medical examining board of the State Medical Society.

Dr. W. T. McKnight of Marlin, Tex., died in Austin February 13, 1910, aged fifty years. He was a graduate of the Vanderbilt University in 1888.

Dr. John W. Warren of Warren, Ark., died at his home on February 12, 1910, aged ninety years. He was a veteran of the Confederate Army.

Dr. Henry J. Waite of Minneapolis, Minn., died February 11, 1910, aged eighty years. He was a graduate of the College of Physicians and Surgeons of Keokuk in 1880.

Dr. William Henry Walling of Atlantic City, N. J., died on February 18 at the age of sixty-four years. He was a graduate from the Medico-Chirurgical College in the Class of 1889.

Dr. Ezekiel W. Cooper of Camden, Del., died on February 21 at the age of 73 years. He was graduated from the medical department of the University of Pennsylvania in the Class of 1866. He was President of the Delaware State Board of Health for several years, also member of the Medical Examining Board representing the State Medical Society. He was a member of the Convention that framed the State Constitution of 1896-97.

Dr. Alonzo M. Barnes of Philadelphia died on February 25 at the age of seventy-three years. He was graduated from Penn Medical University in the Class of 1858. He served through the Civil War as surgeon in the United States Army.

Dr. Marion L. Heffelfinger of Chicota, Tex., died at his home on February 17, 1910, as the result of an injury received six months ago. He was a graduate of the Kentucky School of Medicine in Louisville in 1887.

Dr. William A. Miller of Sheridan, Wyo., died recently, aged 36 years. He was a graduate of Washington University in 1900.

Dr. J. W. Redwine of Winchester, Ill., died at his home recently, aged 51 years. He was a graduate of the Missouri Medical College in 1882.

Dr. Hendricks L. Cartwright of Burkesville, Ky., died February 25, 1910, aged 55 years. He was a graduate of the University of Louisville in 1878 and was a member of the Cumberland County Medical Society and the Kentucky State Medical Association.

Dr. George M. Reddish of Somerset, Ky., died in Oklahoma City, February 19, 1910, aged 56 years. He was a graduate of the University of Louisville in 1885, and was a member of the Pulaski County Medical Society, the Kentucky State Medical Association and the American Medical Association.

Dr. Henry T. Willis of Shelbina, Mo., died at his home on February 25, 1910, aged 56 years. He was a graduate of the University Medical College of Kansas City in 1898 and was secretary of the Shelby County Medical Society.

Dr. Charles B. Hawley of Gouverneur, N. Y., died on February 28, 1910, aged 63 years. He was a graduate of the Cincinnati College of Medicine and Surgery in 1871, and a member of the St. Lawrence County Medical Society and the Medical Society of the State of New York. Dr. Hawley was for many years Coroner of St. Lawrence County.

Dr. Lewis O. Flexer died at Delano, Schuylkill Co., Pa., on February 28, of erysipelas, at the age of 57 years. He was graduated from the Department of Medicine and Surgery of the University of Michigan in the Class of 1879.

Dr. Robert Henry Golder of Rossville, Borough of Richmond, New York City, died at his home March 6, 1910, aged 89 years. He was a graduate of the medical department of New York University in 1851, and was a member of the Richmond County Medical Society and the Medical Society of the County of New York.

Dr. A. C. Godfrey of Brighton, Colo., died at his parents' home in Galena, Ills., on February 25, of tuberculosis. He was in practice for a number of years in Lander, Wyo., and three years ago went to Brighton in search of health. A year ago ill health forced him to abandon practice and he returned to Galena. Dr. Godfrey was 41 years old and was a graduate of Rush Medical College, Chicago, in the class of 1891.

COLORED RACES — POLONIUM — RADIUM AND CANCER — AFTER-CARE OF INSANE PATIENTS — INSTITUTE OF HYGIENE — PSYCHOTHERAPEUTICS AND HYPNOTISM—U. C. S. CHEMICAL DEPARTMENT—OBITUARY.

London, February 18, 1910.

At the Royal College of Surgeons on Monday Dr. Arthur Keith, Conservator of the Museum, opened a course of Hunterian lectures on the "Anatomy and Relationship of the Negro and Negroid Races." The day was the 182d anniversary of Hunter's birth, and the lecturer marked it by showing a lantern picture of his portrait by Reynolds, which hangs in the council chamber of the college, and also made some remarks on the Hunterian collection in the museum. Passing to his subject, he thought the first important work concerned with it was Prichard's "Researches into the Physical History of Mankind," published in 1813. Dr. Prichard, a physician in Bristol, he pronounced to be the greatest anthropologist of his time who anticipated many of Darwin's conclusions. He was clearly influenced by Hunter's experiments and teaching as to the higher races being variants of the darker, probably a result of civilization. A further advance was marked by Sir William Lawrence's Hunterian lectures (1818), which raised a storm of indignation when they were issued in book form. But public opinion changed, and in 1865 Huxley declared Lawrence one of the ablest men he had known and his book as one that "might be read in a Sunday-school without surprising any one." Lawrence concluded that there was only one species of man, the negro being a variety, distinctly inferior; but this should mark him out for protection rather than oppression. The only other addition to the subject for a long period was made by Dr. Pruner Bey, a physician in Egypt. When Africa began to be opened up anthropologists set to work, and it had been found that, as regards head and body form, the African races exhibit almost as many varieties as Europeans. Fuller knowledge of the Pacific Islands, the Malay Archipelago, and of the Far East had shown that the distribution of a race closely allied to the African was made wider than had been supposed and later discoveries have seemed to extend it much further. The lecturer went on to say that we must revise our methods by substituting for empirical measurements others founded on a scientific basis. He then gave a demonstration with a craniometer designed for the museum work. He proceeded to analyze the nature of the various physical characters of the African races, employing skulls brought from Congoland. They were those of the Batetela tribe, which had been devastated by sleeping sickness. He showed that in the characters of the forehead this and the surrounding tribes were less Simian in type than Europeans. They showed, as Pruner Bey had expressed it, "the characters of a new-born babe above the mouth," but he feared that from what was known of the Batetela that their foreheads belied their practices.

In his next lecture Professor Keith said that up to the present time scientific investigation had failed to find any sharp line of demarcation between the white and colored races. So far as color was concerned, it could be shown that the black of the negro did not show itself in the embryo until about the seventh month, and became more intense with age. There was reason to consider his curly hair was a comparatively late feature, and though it could hardly be called a higher evolution, it might fairly be described as a distinct specialization.

The announcement at the Paris Academy of Sciences that polonium had been isolated from radium has given to the subject of radioactivity and its possible influence on disease a still more intense interest, and may be said to have startled the scientific world as much as the public. The latter is naturally taken up with the estimate that polonium may be considered 5,000 times more rare than radium, that it decomposes organic and in organic bodies with amazing rapidity, that it loses weight and disappears in a short time, half of it having gone in 140 days, while radium takes 1,000 years for its complete transformation.

Sir William Ramsay was entertained at the Authors' Club, and, replying to the toast in his honor, given by

Mr. Rider Haggard, naturally spoke of the subject, and mentioned Mme. Curie's new triumph. He said radioactivity was a new word; in fact, the French Academy had not yet decided on its gender, though it had decided that automobile was masculine. Professor Rutherford and another scientist supposed radium changed entirely into different products, emitting during its decomposition alpha particles. The change seemed to be into a gas or mysterious exhalation, called by Rutherford the "emanation." Here then was radium doing continually what the alchemists tried to do, changing the elements. "How long would radium last if it were always changing?" asked Sir William, and answered "Practically forever." "It looks a paradox, but is not," he added. "We can tell how long it will take radium to half-change into the emanations; we have just measured the time in our laboratory; it is 1,750 years. It could be squeezed into a tube finer than that of any thermometer. It was the most concentrated form of energy known, and its emanations went on changing into other things, to each of which, as it became known, a name was given. There was Radium A, which lived for a quarter of an hour and then changed to Radium B, which in its turn lived three-quarters of an hour. Radium C lived for half an hour. In two or three hours all these three substances had been produced and disappeared. Then came a fairly long-lived substance—Radium D—which was half gone in forty years, giving one time to look at it, and it was a leadlike substance with a metallic lustre. Then there was Radium E_1 and E_2 and Radium F, which was probably identical with the polonium discovered by Mme. Curie in pitchblende. Scientists had now the greatest concentrated energy known," said Sir William, and he doubted if they would ever get greater; but scientists were always in doubt, and he doubted his own assertions. The alpha rays shot out at a rate of between 15,000 and 40,000 miles a second and carried energy, but they had to be caught.

"Up to the present," he went on, "it has been said radium cures cancer. I do not think it by any means certain; I think it exceedingly doubtful; but it has not been rightly tried, and all we can say is that there have been things done which are favorable to that suggestion. But, although we may postpone decision with regard to cancer, there can be no postponement as to rodent ulcer. It is a certain cure for that. There has not been a single case of failure, except when the disease had spread to an awful extent before treatment was begun."

The annual meeting of the After-Care Association for Asylum Patients was held at the College of Physicians, and Sir D. Powell took the chair. The report was encouraging. Last year 8,000 were discharged from asylums, many of them cured. But it is easily to be understood that the return to their previous life must be very trying for them. In these cases the society was a help for the sufferers and a safeguard for the community.

Dr. Savage pointed out that many who had recovered from acute mental disorder might seem reasonable, but were not responsible, and premature return to their duties might lead to recurrence, and he mentioned cases whose health had been confirmed by convalescent homes. Sir W. Collins corroborated, and Sir D. Powell said insane persons were often wonderfully sane on all subjects outside their particular delusions, and could do much work while these were in abeyance.

The annual meeting of the Institute of Hygiene was held on Monday, when an important announcement was made, to the effect that the executive had resolved to appeal for £10,000 to carry on and develop the work. The president, Sir William Bennett, in moving the report, indicated some of the efforts made in the past and the great field of work which yet remained almost untouched. He referred especially to the necessity of educating parents in the ordinary principles of hygiene, and declared thousands of children were doomed to early graves or lives of inefficiency and decay by the ignorance or indifference of their parents. Dr. J. C. Thresh, in seconding the report, dwelt on food and alimentation, and said where the work of medical officers of health ended this society's began with fight for personal hygiene as against ignorance and apathy. Sir George Kekewich followed, referring more especially to cleanliness, baths and the hygiene of schools. Professor Haliburton spoke of admixtures and adulterants of foodstuffs, and particularly of the craze for whiteness in bread, which was now often attained by subjecting flour for a few seconds to the fumes of hydrogen peroxide instead of the old plan of keeping for six or eight weeks. By these fumes inferior bread could be made to appear the best. Surgeon-General Sir Charles Cuffe, Dr. Mayo Robson, and others spoke in commendation of the work of the institute and in support of the appeal.

At the Psycho-Therapeutic Society Dr. Forbes Winslow has been talking (some say twaddling) about the "Suggestive Power of Hypnotism." He said that fashion was only suggestion; in politics many voters were hypnotized by the speaker to do as suggested; in sport if the captain of a team showed apprehension the match was lost before it began. Vice, alcoholism, drug habits were cured by suggestion, as were two-thirds of nervous affections. In fact, the whole world was made up of one huge suggestion, and it often required a strong mind to resist the influence. This assertion reminded one of the Berkleyan contention and the Byronic reply that "when Bishop Berkley said there was no matter, it was no matter what the Bishop said."

University College is appealing to the public for further enlargement of the chemical department. The authorities have secured an option of a suitable site, and propose to erect new buildings to meet the necessities and to utilize the space vacated thereby to go some way toward supplying the deficiency of space for other subjects. As much as £70,000 is asked for. The present laboratories practically date from 1871, although elder alumni will remember still more restricted accommodation and the great expectations entertained as to the lasting sufficiency of the enlargement of that date. But they could not anticipate the rate at which chemistry would advance and the college would become too small. In fact, there was an enlargement in 1902, and the number of students have so increased since that time that some have had to be refused. The average number for the last four sessions has been 261, of whom 160 were juniors, 68 advanced, and 33 research students.

Sir Charles H. Marriott, Consulting Surgeon to the Infirmary of Leicester, where he for many years held a most distinguished position, died on Monday, aged seventy-seven. He took F.R.C.S., 1859, M.B. Lond. the same year, and proceeded to M.D. in 1863.

Dr. T. Kilner Clarke, J.P., also a highly distinguished provincial consultant, died on the 14th, aged sixty-six, at his home, Huddersfield. He took M.A. and M.B. Cantab., 1871, and afterward F.R.C.S., 1872, and M.D.T.C.D., 1873. He was consulting surgeon to the infirmary, and held other important posts. He contributed to the societies and journals on various surgical and gynecological subjects.

The death has also occurred of Surgeon-General Alfred Eteson, C.B., M.D.I.M.S., retired, aged seventy-eight. He served in the Indian Mutiny, 1857-1858, and was mentioned six times in dispatches. He was also in the Afghan War, 1879. He was awarded a medal for each campaign and made a C.B in 1907.

Major A. L. Borradaile, R.A.M.C., retired, died on the 5th inst., aged forty-five. He graduated at Edinburgh, 1886, entered the army the next year, and became major in 1899.

From British East Africa comes the news that Dr. Arthur Frost Forster, F.R.C.P., died suddenly at Katonga on the 3d inst.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

CHARITABLE BEQUESTS—MEDICAL STATISTICS—BALNEOLOGICAL CONGRESS—RADIUM CABINETS.

BERLIN, February 1, 1910.

LAVISH spending for scientific purposes is not uncommon in the United States, but with us it is a great rarity. As far as I know, there has been in Germany no such great sums donated for medical purposes as those which have been given by the Speyer family in Frankfurt. I will therefore give a few of the foundations which Mrs. Franziske Speyer has arranged for in her will. The Georg Speyer House for Experimental Therapeutics received 1,000,000 marks; the city of Frankfurt received 500,000 marks for the care of incurables; for the fight against lupus was given 50,000 marks; for the study of cancer, 30,000 marks; for the building of a hospital, 700,000 marks, and for the Medical Protective Association in Frankfurt, 75,000 marks. The total sum reached 2,500,000 marks.

Dr. Prinzing in Ulm was prompt at the beginning of the new year in producing his statistics concerning the

physicians of Germany. The total number of physicians is 31,969, an increase of 329 over last year. For every 10,000 inhabitants there are almost exactly five physicians. Since the year 1906 this number has decreased as follows: 5.06, 5.06, 5.02, 5.00. In the immediate future, however, we may expect a definite increase in the number of physicians, for since 1905 the number of students has steadily increased. The numbers are here given for the summer term in each year: 6,032, 6,570, 7,574, 8,250 and 9,239 during the last summer term. In the eastern part of the Empire there appears to have been a slight decrease in the number of physicians. The number of specialists also seems to have reached a standstill. In the large cities in 1906, of every 100 physicians 34.6 were specialists; in 1909, 34.3.

The first month of the new year is barely ended, and already the congresses have begun. The first congress of the year was that of the German Balneological Society, which met in Berlin on January 28. In general it may be said that this meeting increases in importance each year. The reason for this is that the bath physicians are obliged to take part in scientific investigations if they wish to have their names known. This has had a great influence in improving the curative factor at the baths. With the increasing knowledge the great clinicians have begun to busy themselves more earnestly with balneological subjects. This year His, the chief of the medical clinic of the University of Berlin, has presented the theme which has been worked out in his laboratory, namely, the therapeutic use of radium. It is already known that radium occurs in various sources in considerable amounts. The main difficulty in the way of experiments with it is the great instability of the active radium emanations. Löwenthal of Braunschweig has endeavored to eliminate this fault. He constructed air-tight chambers in which the patients remained for long periods. In order to prevent respiratory distress the carbon dioxide was absorbed by lime and the oxygen supplied from iron bombs. The overheating and moisture of such chamber was easily combatted by cooling and drying mechanisms. The great advantage of such a chamber lay in the fact that the radium emanations developed therein were always of constant strength, and what was of more importance were absorbed by the human body in the same quantity. By observations lasting for hours it was demonstrated that under the influence of the radium emanations metabolism is increased and that the increase lasts for some time in decreasing amount. Further researches were carried out in gouty individuals. It was here demonstrated that in most cases—but not in all—the increased uric acid content of the blood found at the beginning of the treatment was completely reduced so that the blood became free from uric acid. At the same time some of the patients lost their pain while in the chamber. In order to enable all patients in all localities to use this chamber treatment Löwenthal has constructed an apparatus by which the amount of oxygen needed for one person may be transported in a bag.

(From Our Regular Correspondent.)

DISCUSSION ON TYPHOID FEVER BEFORE THE ACADEMY OF MEDICINE.

PARIS, February 10, 1910.

VINCENT recently made a remarkable report to the Academy of Medicine, on behalf of the permanent commission against epidemics, with reference to the different epidemics which have afflicted France during 1907, and especially on typhoid fever. Though causing a remarkable death rate typhoid is a malady that can be surely prevented. In France it kills from ten to twenty thousand persons annually; in Paris, thanks to the most minute care taken to protect the sources of the water supply, there has been a marked decrease of the mortality from typhoid fever. While thirty years ago there were recorded each year in Paris at least 2,000 deaths from typhoid fever, and in 1882, during an epidemic, the figures rose to 3,214, in 1900 it fell to 1,000. Since 1900, the time when the service for surveillance of the sources of water supply was created, the number of deaths from typhoid has slowly diminished, until in 1908 there were but 226 deaths in Paris. But it is not the same in other cities, and we may say that nothing or almost nothing has been done to protect the country against typhoid fever.

The etiological factors in the transmission of typhoid fever are the same everywhere. Typhoid fever, an exclusively human disease, has for its specific agent the bacillus of Eberth, which lives in the fecal materials or the urine of patients having typhoid fever. But we know that among those who have typhoid the pathogenic microbe multiplies in the blood, and accumulates in the gall-bladder, and may be eliminated at intermittent periods. The patient eliminates the bacillus, not only during several days, several weeks, several months, but several years, after his recovery. There are, then, patients who are chronic typhoid carriers and perpetuate the malady. It is these persons who give birth to unexplained cases, which appear apparently spontaneously in villages, or collectively in families. Soper of Boston relates the case of of a cook who was the cause of 38 cases of typhoid fever in the different families in which she was successively placed. Park of New York has published the case of a cook who, having served eight families, caused 28 cases of contagion. It is by unwashed hands that during the preparation of food these carriers of bacilli may transmit the disease. It is none the less true that of all the causes of typhoid fever the most frequent is the use of contaminated water. The contamination of water results from the projection of typhoid feces into the streams from the toilets along their course, or by easy infiltration of the dejections through the neighboring ground to the streams. Aside from water other intermediaries may propagate the bacillus of Eberth. The preparation of cider necessitates the addition of water to the sweet fruit juice, and this water is generally drawn from the streams. Although the typhoid bacillus disappears in a few days on account of the completion of the fermentation of the cider, it is true that many persons drink cider sweet before fermentation has taken place, and thus receive the typhoid germs. Milk, when it is adulterated with water which contains the bacilli of Eberth, or has been collected in infected vessels, or vessels which have been washed with infected water, may be the source of contamination with typhoid fever. Oysters when they have been placed or preserved in contaminated sea water, especially near the mouths of sewers, become the source of infection with typhoid fever. Among the numerous causes which contribute to the distribution of typhoid fever in the country is the deplorable custom of fertilizing with human dejections the fields, which exists in certain parts of the country. The vegetables are treated every day with the precious fertilizer, which is carefully poured over them with a spoon. Thus vegetables, salads, cresses, tomatoes, radishes, cucumbers and strawberries, consumed in a raw state may become the origin of cases of typhoid fever. As general prophylactic measures against typhoid fever Professor Vincent advocates the hygienic education of the populace and the perfecting of the epidemiological studies of the medical profession. Best to fight against typhoid it will be necessary to create laboratories of epidemiology and bacteriology. He demands also the isolation very early of all the sick as completely as possible. This isolation should be preceded by the declaration of the infection. Further, disinfection is indispensable; it should be carried out with everything that has been contaminated by human fecal materials, by urine, or the expectoration of the typhoid patient. As to measures to be taken with reference to the carriers of typhoid, it would be useful to give them instruction as to the prophylactic measures that should be employed to prevent contagion. Finally, since all foods can be contaminated either by the hands or by flies the methods of protection of foods should be indicated. Since vegetables that are eaten raw may be the carriers of bacilli, in time of epidemic it is necessary to abstain from them or to eat them cooked. Delorme insisted above all on the importance of drinking water as a vehicle of typhoid fever when polluted. The influence of bacillus carriers, whether latent or healthy, is according to him exceptional. Vaillard does not agree with this. He believes that we should take cognizance of bacillus carriers in taking the necessary measures, giving them neither too much nor too little attention. Chantmesse believes that the genesis of typhoid fever is mostly dependent on polluted water, but we must take great care with reference to carriers of bacilli. As prophylactic measures he asks for the assurance of the purity of potable waters, the removal from danger of foods that may be contaminated with impure water, and the increase of human resistance by care of the health. Finally, Chantmesse advises vaccination against typhoid fever.

Widal recalls that it is the reaction of agglutination discovered by himself that permits us to make the diagnosis of typhoid fever. The serodiagnosis of Widal shows that there is but one bacillus of typhoid fever, the bacillus of Eberth, which is absolutely specific for typhoid fever.

Kelsch thinks that exclusively antibacillary prophylaxis of typhoid fever is rationally insufficient. The microbes that are within us are often reduced to silence and deprived of their special functions. The determination of the factors which create or exalt their virulence is not less important than the search to discover them. Fatigue and overwork play an important part in the causation of typhoid fever. Netter thinks that at the present time we do not possess a vaccine which is free from local and general accidents resulting from the inoculation. He believes that we should practice vaccination in all localities in which typhoid fever does not exist; only persons in good health should be submitted to the test, and we should avoid over-exertion during the first few days after the inoculation, and should not send the subjects into infected localities until ten to fifteen days after the inoculation. Experience has demonstrated that those who have undergone typhoid vaccination acquire an immunity that is very appreciable and among them typhoid fever is sensibly attenuated.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

SPECIFIC TREATMENT OF CARCINOMA—HOSPITAL CONSTRUCTION—THE NEW SANITARY SEWER—MEETING OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE—PERSONAL.

MANILA, P. I., January 17, 1910.

THE regular monthly meeting of the Manila Medical Society was held at the Philippine Medical School, January 3, 1910, at 8:30 P.M. A paper entitled "Specific Treatment of Carcinoma," by Drs. Coca and Gilman, was read by Dr. Philip Gilman, Professor of Surgery at the Philippine Medical School. This paper was of most unusual interest in that no less than six persons diagnosed as carcinoma were presented who had been treated by the injection method, and who were apparently cured. The diagnosis of carcinoma was reported to have been confirmed microscopically in each instance. The authors stated that this report was only intended to be a preliminary announcement and the exact details of the method used would be reserved for a later time. It may be stated, however, that the treatment is based on the vaccine principle. An incision is made into the carcinomatous mass, a few cancerous nodules are removed, and these are thoroughly ground up, after which they are placed into salt solution, and this latter is injected into the patient. Within a few days the cancerous growth becomes less hard and then gradually undergoes resolution and finally absorption. The glandular involvement also slowly recedes, the whole process taking only several weeks. As a rule, only one injection is given.

At this meeting the annual election for officers of the society was held, with the following result: *President,* Dr. Vernon L. Andrews; *Vice-President,* Dr. Philip Gilman; *Secretary-Treasurer,* Dr. Coca; *Member of the Council,* Dr. E. R. Stitt, U.S.N. After considerable discussion, the society voted to increase the Bulletin of the Manila Medical Society from a four-page leaflet to a sixteen-page publication, to be issued monthly, the same as heretofore.

The need of constructing hospitals in the provinces of the Philippines has been recognized by all the different medical men who have had charge, directly or indirectly, of insular health administration ever since American occupation of the Philippines took place. Requests for appropriations for such projects were presented to the Legislature a number of times each year, but without result. At the last Legislature, however, a law was passed by which the Governor-General was given authority to use such balances as a bureau might have saved from its appropriations for the construction of public works. Such a measure has been anticipated by the officials in charge of the Bureau of Health for a number of years and a balance has been available for this purpose. Recommendation was immediately made to the Governor-General for using some of this fund in the construction of hospitals which have been so urgently needed, and it is therefore most satisfactory to state that this need has now been finally recognized, and for this purpose the sum of approximately $40,500 has been set aside for the purchase of a site in the City of Cebu and the construction of a modern hospital at that place. As Cebu is the center of a population of nearly three million, a hospital there will obviously have a wide field of usefulness. The plans are in course of preparation, and it is possible that the end of the present year will see the accomplishment of this most desirable project. It is expected that the provinces benefited will endow beds and thereby assist in maintaining the hospital after it is once constructed. Several provinces have already signified their willingness to appropriate funds for a number of endowment beds.

Since the new sanitary sewer has been ready for service there have been a total of 211 connections made. It is apparent, however, that unless the number of connections made increase very rapidly that the present rate only keeps pace with the natural growth and development of the city, and therefore no great improvement can be expected. One of the principal difficulties at present seems to be that there are not enough persons engaged in this business to handle the work promptly or a sufficient supply of materials available.

Preparations for the first biennial meeting of the Far Eastern Association of Tropical Medicine, which is to hold its first session in Manila March 5, 1910, are now being actively carried on. All governments in the Eastern Hemisphere have been invited to take part, and information has already been received from a number of countries that they will send medical representatives. This will probably be a larger gathering of medical men who are actually engaged in tropical medicine than has ever taken place.

Major Charles E. Woodruff of the United States Army Medical Corps, who only recently arrived in the islands for his regular tour of duty, has, on account of illness, been compelled to return to the United States.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 24, 1910.

Scarlet Fever Prophylaxis with Streptococcus Vaccine.—Richard M. Smith reviews the work that has been done in the endeavor to secure immunity from scarlet fever, most of the accounts having been published in Russian. The vaccine most widely used was a concentrated bouillon culture of the streptococcus isolated from a person ill with scarlet fever, killed by heating to 60° C., with the addition of 0.5 per cent. carbolic acid. The scale of dosage used by Gabritschewsky and most of the other investigators is 0.5 c.c. of the concentrated bouillon culture for children two to ten years old. For those younger one-half this amount and for adults twice the amount is used. Another method is 0.1 ccm. for each year of the child's age, with 0.25 ccm. as the minimum and 1 ccm. as the maximum. It is claimed that after three doses of the vaccine, and usually after two, a complete immunity is established against scarlet fever. The duration of the immunity is thus far entirely a matter of speculation. It is thought by the closest observers that the immunity lasts at least one and one-half years. The reports of the use of this vaccine in Russian villages during epidemics seem to show that one injection of the vaccine greatly reduces the liability to the disease; children that received two injections were very rarely attacked and there were no cases among those who had had three injections, except one child who was vaccinated during the inoculation period of the disease. From the reports of these Russian physicians where the number of cases vaccinated runs into the hundreds it seems evident that the streptococcus vaccines, used as advocated by Gabritschewsky, have some influence in controlling scarlet fever. Their use, with proper care, is attended by no harmful results. They should be given a wider application in this country to prove or disprove the contentions of the Russian physicians.

A Case of Alcoholic Cirrhosis in a Boy of Four Years.—David N. Blakely reported this case because it did not seem to fit into any of the classes of cirrhosis usually given unless it might be the "fatty cirrhotic liver" to which Osler refers as found most frequently in beer drinkers. The conditions present were at least infrequent. The child was four and one-half years old, the first child of healthy parents, and in good health until last June. The onset of his illness was indefinite but he grew slowly but steadily worse. In October when Dr. Blakely saw him he presented no abnormality excepting that his liver was symmetrically enlarged, nearly down to the level of the umbilicus in the mid-clavicular line. The spleen was not palpable. The surface of the liver was even and smooth, and there were never any irregularities felt. There was no jaundice and no history of any; none developed later. The liver continued to enlarge until the time of his death on November 25, 1909, when it extended about an inch below the umbilicus in the mid-clavicular line. There was

an increasing loss of appetite but no disturbance of digestion. The urine showed concentration, excess of urates, and the slightest possible trace of albumen. During the last two weeks of the child's life there was slight edema of both upper and lower extremities. There was no palpable ascites and the spleen was at no time palpable. The cause of this enlargement was not apparent until it was learned that the father was accustomed to have beer and whiskey and it seems that from the time this child was able to drink from a glass he was given some with the others. This probably continued over a period of nearly two years but the amount taken at any one time was never large.

New York Medical Journal, February 26, 1910.

The Management of Glycosuria in Elderly Persons.—Victor C. Vaughn is of the opinion that the glycosuria of elderly life is due in many instances to excessive carbohydrate feeding; this excess is usually confined to some special carbohydrates, sugar, and wheat starch; the early glycosuric of this class is often able to care for other carbohydrate foods; the harmful carbohydrates should be detected and eliminated from the food; those that can be assimilated should be determined and permitted; there is a specificity in the metabolism of carbohydrates, as there is in that of proteins; the presence of a small amount of sugar in the urine (from 0.5 to 2 per cent.) should not be regarded as a matter of trivial importance. Dr. Vaughn finds that most writers of the subject fail to refer to the fact that in many persons the capacity of assimilating carbohydrates is largely determined by the time of day when the food is taken. Glycosurics who cannot metabolize carbohydrates when taken for breakfast may dispose of one hundred grams of bread when taken at six o'clock dinner. Why this is true he cannot explain, unless it is due to the more hurried way in which both foods and medicines pass through the body when taken in the morning. Another point emphasized is the importance of open air treatment of this form of glycosuria. In a general way it is stated by most authorities on diabetes that life in the open air is beneficial, but this point has not been sufficiently emphasized. Porch sleeping is quite as beneficial to the glycosuric as to the tuberculous.

Cases of Chronic Joint Troubles.—J. Madison Taylor relates his experiences with a number of cases of arthritis deformans in which he secured more satisfactory results than are usually attained by patient and persistent employment of massage and passive motion. While the measures that served him well were simple they were varied in accordance with the individual peculiarities of mind and body. They were as far as possible such measures as the sufferer would accept and to which he would lend his cooperation. The cases served to show what could be done by insistence and persistence with measures well within the reach of all. Physicians, too, often failed to recognize the incipience of rhumatoid disorders or to realize their gravity. The real peril lies in the vacillation and unwillingness of the patient to submit to systematic guidance. In the numerous cases of subacute stiffenings, joint pains, etc., which can be called "rheumatic gout" he has secured the best results from steady use of thyroid extract, which, as Sajous states, enhances general metabolism and nutrition, in all organs, increases the defensive agents in the blood in proportion, and facilitates the bactericidal and antitoxic process.

Inflammatory and Suppurative Conditions of the Retropharynx of Infants.—Dr. E. Mather Sill states that the anatomical structure of the parts in the retropharynx makes infection comparatively easy in infancy. Retropharyngeal adenitis or abscess although not uncommon is frequently overlooked or incorrectly diagnosticated in infants. It was, as a rule, gradual or insidious in its onset, being usually from one to three weeks in developing. In making digital examination great gentleness should be used to avoid rupturing the abscess and no gag should ever be inserted into the mouth as forced stretching of the jaws might result in rupturing the abscess, which might cause sudden death from aspiration of pus. Spontaneous rupture into the air passages was a common cause of death in this affection. Unless the child was very young or marasmic the prognosis if operation was performed was good. The majority of cases of retropharyngeal adenitis terminating in abscess occur during the first year of life. Of 49 of Dr. Sill's cases 19 were over one year and 30 were one year and younger. Twenty-six patients were six months to one year. The oldest patient seen was three years old. These observations correspond with those of other observers. Where there is a hard non-fluctuating tumor, hot compresses may be applied to hasten the softening. As soon as fluctuation is detected evacuation of the abscess should be performed. One should never wait for spontaneous opening. The child is held in the upright position during operation and as soon as the knife has been plunged in the head should be lowered and the pus allowed to drain from the mouth. Where the child is small the incision is not easy and should not be attempted by unskilled hands.

Report of Certain Lumbar Punctures at Bloomingdale Hospital.—The object of this contribution by George S. Amsden is to present the results of careful investigation in thirty-seven cases in which lumbar puncture has been made. In one case, owing to faulty technique, no conclusion was reached. Of the remaining 36 cases, 29 patients were at some time while in the hospital diagnosticated as paretics, tabetics, or cases of acquired syphilis. The seven remaining cases were paranoia, one; dementia præcox, two; mania, three; senile psychosis, one. The clinical diagnosis and the results of spinal fluid examination agree now in 80 per cent. of the cases. In an estimation, therefore, of the practical working value of the spinal fluid examination, it seemed to him that the results, as well as the published data on the subject, leave them in little doubt. This procedure offers in appropriate cases evidence almost as objective as the pulse or temperature, and was of decided value.

Journal of the American Medical Association, February 26, 1910.

Kidney and Ureteral Stones.—A. D. Bevan says that kidney stone surgery affords an admirable opportunity for team work, by which alone, he claims, can the best results be obtained in this special branch of surgery. In 1897 he first used the *x*-ray for the successful diagnosis of kidney stones. Since that time he has operated on more than 60 patients, using the *x*-ray to confirm the diagnosis, and he offers some of his conclusions gained by this clinical experience. He thinks that it is most probable that kidney stones are due to a low grade mycotic infection and that the germ forms are probably colon and typhoid. Kidney stones may exist latent in the kidneys, giving rise to no symptoms, though not so frequently as gall-stones. They may cause symptoms in two ways: by favoring infection or mechanically by obstructing the ureter. The passage of a stone through the ureter does not necessarily cause any pain; the cause of renal colic is the greatly increased intrarenal tension due to plugging the ureter. The passage of the stone is not due to pressure from behind but to the peristaltic action of the muscular fibers of the ureter. In his series of cases he has had a number of atypical ones, simulating appendicitis or gallstone disease, ileus, and stomach trouble. It is rare that an exact and positive diagnosis is made by any one method, though a clinical diagnosis can be made often from the history of colic and blood and pus in the urine. His main reliance seems to be on the *x*-ray, in the use of which, with good technique, the percentage of error, he thinks, will be less than five. In the kidney region there is seldom any localized deposit or other pathological formation giving a shadow except calculus. As regards treatment, he states that operation and removal of the stone are indicated in all cases showing the presence of one or more large stones, the passage of which is improbable; after the failure of medical treatment or the repeated trials of local treatment (lubricants and local anesthesia); and with anuria present for forty-eight hours or more. There are only two contraindications to operation, namely, advanced age and bad condition from organic disease, and second, very small stones in the ureter that can reasonably be expected to pass. Pyelotomy is the operation of choice with small stones in the pelvis or a fair-sized one limited to the pelvis. Nephrolithotomy is the operation for multiple stones, stones in the upper or lower pelvis, stones in the calyces, or branched stones or stones with gross infection. Nephrectomy is the third operation for badly diseased kidneys, and Bevan's results have improved since he has recognized more than formerly the necessity of a primary nephrectomy in such cases. The operations are described. He cautions against the use of nitrous oxid anesthesia in bad heart cases, in which he considers it less safe than ether. He thinks this fact should be more widely known than it seems to be at present. With an expert anesthetist he usually prefers ether. Judging the prognosis from his own cases, he has had but one death in over fifty cases of pyelotomy and nephrolithotomy. He has had three deaths, however, from secondary nephrectomy, both difficult on account of the need of digging the kidney remnant out of dense scar tissue.

Aerophagia.—D. Vanderhoof concludes as follows: "1. Aerophagia is a well-known clinical phenomenon, seen

in its most characteristic form in cases of hysteria. 2. It occurs, however, in normal individuals, and is a most common sympton in functional stomach disorders. 3. In such cases its significance is very frequently misinterpreted as being due to some form of fermentative dyspepsia. 4. Actual fermentation in the gastrointestinaal tract is a rare occurrence, and never gives rise to the excessive quantities of gas that are expelled by the aerophagic patient. 5. Aerophagia is a neurosis associated with a loss of tone in the muscular walls of the stomach, so that the organ is easily inflated by air swallowed with food or between meals. 6. It is entirely independent of the character of the gastric secretions, and occurs relatively as frequently in patients with anacidity as in those with an excess of hydrochloric acid. 7. It does not depend on what the patient eats, but on the condition of the stomach nerves when he eats. 8. The treatment of the condition, after excluding all organic diseases and correcting all possible reflex causes, consists principally in explaining to the patient that the gas he eructates is not due to fermentation, but that it is atmospheric air that he unconsciously swallows."

Uniform Health Laws.—The distrust of federal supervision in health matters will, in the opinion of Joseph Y. Porter, always be a hindrance to a salutary national administration in such matters. He even questions the laws which have been enacted regarding maritime quarantine as being proof against objection on constitutional grounds, though they have been acquiesced in by the States. The success obtained by Gorgas in Havana in eliminating yellow fever and inaugurating a model system of sanitation in Cuba could never have been obtained under our form of government and was not so easily obtained even under the regulations in Panama. He sees the remedy for this state of affairs only in the adoption of a constitutional amendment permitting congress to supervise and control all matters relating to the public health. It is not believed by him that there will be any objection raised sufficient to prevent the ratification of such an amendment. He would not take away from the States their own powers, which should be left to them so far as possible, but would prevent the conflicts of authority which now arise.

Virulence of Bacillus Mallei.—B. L. Arms reports experiments made on the retention of virulence of *B. mallei* under different conditions of culture and subculture. A statement in regard to the rapidity with which the virulence of subcultures of *B. mallei* is lost, by Marshall (Eleventh Rep. Mich. Acad. Sc., 1909), instigated these experiments, which proved that the organism could live in glycerin broth and retain its virulence for at least two months even when kept at body temperature. It was also proved that a culture of *B. mallei* may be virulent after growing on potato for at least a month and that some strains retain their virulence through a great many subcultures on artificial media. The animals employed in the experiment were guinea-pigs. *Bacillus mallei* is an organism handled frequently by many laboratory workers; consequently any fallacy in regard to loss of virulence in old cultures should be corrected, since if one strain is proved virulent, all should be regarded as such unless proved to be otherwise.

Mesenteric Embolism.—F. A. Carmichael reports a case of embolism of the superior mesenteric artery and discusses the nature and gravity of the condition. It is of interest because of its rarity, the extreme urgency of its symptoms, and imperative need of an early diagnosis, and the difficulty of the surgical treatment. In this case death occurred before the intended operation could be performed. The superior mesenteric artery was occluded at a point between the colica media and colica dextra. The portion of the duodenum supplied by the gastroduodenalis was not involved but the entire small intestine except the duodenum was gangrenous. The embolism was assumed to originate from an endocarditis following rheumatism. As there is nothing in the symptomatology to indicate the extent of the infarction the abdomen must be opened before this can be determined and there is danger that after operation, parts seriously involved, as regards their circulation, may be left and cause further trouble. If the entire small intestine is involved the case is evidently hopeless.

The Lancet, February 19, 1910.

The Results of Remineralization in Conditions of Faulty Metabolism, Such as Neurasthenia, Etc.—Hubert Higgins records observations he has made mainly with the object of answering the following questions: 1. Is it possible to arrive at a numerical formula indicating the "state of matter" of the somatic protoplasm? 2. Is chlorine retained in the tissues so as to preserve the balance of colloids and crystalloids when there is a deficiency of phosphorus? 3. Which observations can be relied upon as a guide to successful treatment and the limit of its duration? In one case a group of characteristic measurements were found that showed no indication of variation and instability until a "remineralization" mixture was added to the ration. He has been successful in causing the elimination of parenchymatous chlorine, and in altering the tissues so that its tendency to retention is either lost or considerably diminished. Case records were presented on which was based his thesis. Glénard first described the conditions under consideration and a drawing of chronic spasm of the colon (after Glénard), showing the contracted transverse and descending colon and the splenic pouch, is reproduced. If his experience of twenty-five years could be summed up in a few words, it would be that if these patients were properly fed, provided with a belt, and purged, they will recover. There is absolute necessity for mechanical support in these cases and it was very important to bear in mind the value of saline purgatives. Glénard states that he has seen nothing but good effects by their use "for indefinite periods." He has no hesitation in attributing these conditions to the effects of cumulative action of the toxins produced by cold, fatigue, and autointoxication. These patients should be made to understand that they are not suffering from "nerves" but from a serious condition of vicious metabolism.

Infantile Types of the Temporal Bone and Their Surgical Importance.—Arthur H. Cheatle applies the term "infantile" to those bones which retain throughout life the characteristics of the outer antral wall and mastoid mass as seen in infancy. There are two types in infancy, one in which mastoid mass is diploetic, and one in which the mastoid mass is dense. The surgical importance is the same in both forms and may be considered under two heads: 1. Influence in cases of suppuration in the antrum. In his opinion the anatomical conditions seen in the infantile types are factors in producing chronic suppuration and the dense outer wall of the antrum is one of the factors and not the result. If one were given the choice of temporal bones, preference would be given to the cellular type as being safer in case of infection of the antrum. 2. Influence in operations for suppuration. Apart from the difficulty of opening the antrum on account of the density of its outer wall, one must always expect to find a forward lateral sinus, and the antrum may be very small or highly placed, or both, and the middle fossa may dip down. In cases in which signs and symptoms of acute suppuration in the antrum are present without pronounced symptoms behind the ear it is wise to open the antrum first and not the mastoid process.

The Lymphatics of the Testicle.—J. Kay Jamieson and J. F. Dobson consider the possibility of removing the lymphatic glands of the testis in malignant disease and define the extent of the "lymphatic area" of the testis. Malignant disease of the testicle is an exceedingly fatal affection; recurrences manifest themselves in the lumbar glands and visceral metastases are frequent. Reference to the description and drawings of the lymphatics will show that the only effective method of removing the lumbar glands would be to strip the aorta and vena cava, the common iliac vessels, the proximal third or so of the external iliac vessels, and the trunk of the inferior mesenteric artery, of all the cellulofatty tissues. They conclude that the arrangement of the lymphatics of the testes is such that the complete removal of the "lymphatic area" is exceedingly difficult and dangerous, if not impracticable.

Perforative Peritonitis Originating in Pouches of the Large Intestine.—Gordon Taylor and C. E. Lakin suggest that this complication must be more frequent than is perhaps usually held since three out of five cases which have come under their observation during the last three years have been cases of perforative peritonitis. They report three cases. Attention has been called to the fact that left-sided abdominal pain of sudden onset may arise in connection with perforation of a sigmoid diverticulum, but perforation of a pouch in the ascending colon, as in one of the cases they report, shows that this exceptional occurrence must be added to the category of pathological phenomena associated with pain commencing on the right side of the abdomen.

British Medical Journal, February 19, 1910.

Effect of Bacterial Vaccines on Nutrition.—Lewis Campbell Bruce says it may be taken as a fact that 90 per

cent. of the sufferers from functional nervous disorders are thin and poorly nourished. In many of the acute insanities, notably maniacal states, the relation of the nitrogen excreted and the urea-nitrogen of the food ingested conforms to that noticed in acute febrile diseases. This suggested that it might be well worth while to try vaccine treatment in such cases. He used a polyvalent vaccine from seven different varieties of streptococci and treated eleven cases of mania with injections of from seven to ten million cocci given at intervals of a fortnight. Eight of these cases had been ill for over a year. Of these two recovered, and two also of the more recent cases. He was impressed with the fact that eight of these cases markedly increased in weight, the increase being after the first injection, and continuing a considerable time after the vaccine had been discontinued; after the stimulating effects of the vaccine had passed off, weight was again lost. He explained this by Ehrlich's theory of cell nutrition. When toxin molecules in the form of vaccines are introduced in suitable quantities the cells are stimulated to produce an excess of side-chains which not only combine with the toxin molecules but also is suitable food atoms presented to them by the blood plasma. Later he has made further observations noting the effects of various vaccines on the body weight of patients under treatment, and feels satisfied that in some cases of obstinate malnutrition vaccine injections improve the general nutrition.

Causes Determining the Production and Distribution of the Eruption in Typhoid Fever.—J. P. H. Greenhalgh shows that the skin area having the same innervation as the small intestine and spleen coincides with the area to which the eruption in typhoid fever is, as a rule, confined. He shows that in this area there is a diminution of tactile sensibility and also a striking loss of vascular tone in the skin. The long latent period, persistence, and slowness in fading of the cerebral streak point to its being a vasodilator reflex. Dr. Cayley has regarded the persistence of the cerebral streak as indicating that the intestinal lesions have not yet healed, which is equivalent to the proposition that the inhibition of the vasoconstrictor and other nerves in the reflex zone in typhoid fever is due to the reflex incidence on them of specific impulses originating in the small intestine, mesenteric glands, and spleen. The influx of a greater volume of blood to the skin in the reflex zone brings a correspondingly greater number of bacilli to the cutaneous capillaries, where the sluggish flow of blood and the impaired resistance of the endothelial cells permit them to loiter in the capillary network. There they are joined by others and this assembly of bacilli sends up inflammation, which becomes visible as the circular, slightly raised rose spots, fading on pressure.

Value of Ball's Operation for Pruritus Ani.—Two cases are reported by Patrick Leighton, both of which were followed by immediate relief after several years of suffering. The object of the operation is to give the nerve terminations in the skin a rest by dividing the trunks, the vicious circle is broken, and the itching does not come back even after the sensation is reestablished. He employed Dr. Ball's method with especial attention paid to the following details: After placing the patient in the exaggerated lithotomy position, the pelvis was raised. This position was of great help in under cutting the posterior pedicle. A plug of gauze was introduced into the rectum to prevent soiling if the patient strained. In cutting the flaps care is taken to include a layer of subcutaneous tissue in order to insure the vitality of the skin and thus avoid sloughing; buttonholing the anal canal leading to fistula is also avoided. The sutures of fishing gut are left long and twisted in a bunch on each side to prevent pricking.

Berliner klinische Wochenschrift, February 7, 1910.

Icterus Syphiliticus Præcox.—Buschke says that there are two forms of liver diseases which occur in the early stages of syphilis, syphilitic jaundice and acute yellow atrophy. The syphilitic jaundice clinically resembles catarrhal jaundice but differs in responding to mercury treatment. It is considered to be caused by a tubercular infiltration of the gall passages or of their compression by swollen lymph glands in the portal region. It is a benign complication of early syphilis. Acute yellow atrophy is usually fatal. The author reports a case of early syphilis which responded well to mercury injection. After the sixth injection he developed a jaundice which appeared to be a rather marked simple syphilitic icterus. On the fourteenth day, however, leucin and tyrosin were found in the urine. The patient recovered. The author believes that the case was one of primary syphilitic parenchymatous hepatitis standing midway between the simple syphilitic jaundice and acute yellow atrophy.

Münchener medizinische Wochenschrift, February 1, 1910.

Further Report on Monkey Poliomyelitis.—Römer confirms the statement that poliomyelitis can be given to no animal except monkeys. His results were as follows in intracerebral injection: With cerebrospinal fluid *nil;* with spinal cord of spontaneous poliomyelitis, three times with positive results, twice without; with spinal cord from experimental monkey poliomyelitis, five times with results, once without. The combined intracerebral and intraperitoneal injection appeared to be the surest method of producing experimental poliomyelitis. The incubation stage in monkeys lasted from six to twelve days. There were no characteristic prodromals. The paralysis came on rapidly. Very acute cases resembled Landry's paralysis in man. The paralysis usually began in one hind leg. The clinical picture of the disease closely resembled that in man. The virus is not yet known. There is some clinical evidence from epidemics that there may be a natural immunity to the disease. Römer has studied the question of artificial immunity in monkeys. His results show that in a monkey that, though injected, has not acquired the disease, a second injection seventeen days later produced a rapidly fatal attack, suggesting a hypersensitiveness to the virus, whereas if the second injection were postponed to the twenty-sixth day an immunity was produced. The results evidently suggest the possibility of there having been a vaccination.

Deutsche medizinische Wochenschrift, February 10, 1910.

The Loss of Water in Obesity Cures.—Reiss and Meyer have carried on a series of metabolism experiments upon persons undergoing various obesity cures, with the especial purpose of studying the water content of the body under the various methods of treatment. They summarize their results as follows: The milk cure causes, besides a destruction of fat and albumen, a loss of water which, especially at the onset of the treatment, causes an appreciable portion of the total loss of weight. Free drinking of water does not decrease the loss of tissue water during the milk cure. On the contrary, in the Rosenfeld mixed diet obesity cure water is in general retained. The cause of this variation in the water excretion under these two methods lies in the salt content of the two diets. If one adds salt to the milk diet and gives the Rosenfeld diet with little salt the water balance is reversed. These opposing relations of salt and water metabolism depend upon abnormal osmotic relations. In addition to this, however, Reiss and Meyer suggest that the water and salt balance may also be influenced by the processes of digestion and intermediary metabolism.

Blood Examination in Basedow's Disease.—Roth has made a number of blood counts on patients suffering from exophthalmic goiter and finds that blood changes are present in most of them. The hemoglobin content is low, the red blood count normal or slightly elevated, and besides a leucopenia there is a lymphocytosis and mononucleosis. Intercurrent febrile diseases change the blood picture in that the leucocyte count increases and the lymphocytosis disappears or decreases. The mononucleosis, is, however, always present. Basing his conclusions on the results of these blood counts, Roth says that, in the diagnosis of the abortive forms of exophthalmic goiter the differential blood count is undoubtedly of very considerable value.

Periostitis of the Epicondyle of the Humerus.—Momburg reports 14 such cases. He says the complaint of such patients is always the same. The pain in the elbow is at first slight and barely noticed. Using the arm causes the pain to increase so that the patient has to give up work. The pain is felt from the epicondyle down to the fingers and sometimes up to the shoulder. It is especially severe during pronation, supination, and flexion and extension of the hand and fingers. The objective signs are slight. There is always marked tenderness over the epicondyle and skin changes are noted over this spot. In some cases a local swelling of the periosteum can be made out. The *x*-ray shows nothing. It usually affects the external epicondyle of the right arm. In nine cases the condition followed a severe strain of the arm; in three, a direct trauma. Six cases were in men, eight in women. Twelve times it occurred in the right arm; twice in the left. In every case it was the external epicondyle. He believes the condition is a periostitis due to direct injury or to muscle strain. The treatment consists in immobilization of the arm and painting of the epicondyle with strong tincture of iodine. Recovery is very slow.

Book Reviews.

URGENT SURGERY. By FELIX LEJARS, Professeur Agrégé à la Faculté de Médecine de Paris, Chirurgien de l'Hôpital Saint-Antoine, Membre de la Société de Chirurgie. Translated from the Sixth French Edition by WILLIAM S. DICKIE, F.R.C.S.; Surgeon North Riding Infirmary, Middlesbrough; Consulting Surgeon Middlesbrough Union Infirmary; Consulting Surgeon Eston Hospital. Vol. I. With 20 full-page plates and 994 illustrations. New York: William Wood & Company, 1910.

THE advance of surgical knowledge during recent years has extended the number of clinical conditions demanding immediate surgical intervention. Formerly urgent surgery meant merely the surgery of injuries, but the size of the book here noted shows that the indications have been increased and multiplied. The present translation has been made from the latest, the sixth, French edition. The first volume includes the surgery of the head, neck, chest, spine, and abdomen, with an introductory chapter on surgical methods and anesthesia. A very literal translation of the French text is given, and the attempt in many places to adhere to a colloquial style is not always productive of a satisfactory result; the translation, therefore, though adequate, leaves something to be desired. The illustrations, however, are excellent, and deserve especial commendation. As French methods are almost exclusively referred to, a very good insight is afforded into their characteristics. One concludes after reading this work that there are but few operative procedures which the writer has failed to include under the general designation of "urgent surgery." In fact, the book constitutes a most complete manual of surgical procedure, and may be safely commended to the attention of the profession. An interesting feature is the number of clinical illustrations, usually from the author's personal experience, which have been included to elucidate some of the salient features in the text. The appearance of the second volume will be awaited with interest.

THOSE NERVES. By GEORGE LINCOLN WALTON, M.D., Consulting Neurologist to the Massachusetts General Hospital; Author of "Why Worry?" "Glories, Pleasures, Pomps, Delights, and Ease Can but Please Outward Senses When the Mind Is Untroubled or by Peace Refined"—John Ford. Philadelphia and London; J. B. Lippincott Company, 1909.

"WHAT is it, then," says Epictetus, "that oppresses and makes us beside ourselves? Why, what else but our own impressions?" This may be taken as a sort of text of this little book, which is a sequel of the author's first publication, entitled, "Why Worry?" The subjects therein introduced are here further elaborated, and many useful suggestions for the nervous and distraught are presented in a convincing and delightful way. The specific mission of the book, the author states, is "in line with the present trend in favor of treating—or, preferably, of preventing—mental disorders by mental methods." The laity seem to have a constant craving for books on medical topics, and we are often at a loss to know what may be recommended. Apparently this book is of the right sort for such a purpose. It would be well for the practitioner to scan its pages, of course, before "prescribing" it for any specific case, the same as he would examine any other book. In doing so he will be personally repaid, however, for he will find it brimful of paragraphs bearing on most common and controllable conditions of mind and body, some of which may be peculiar to himself. Self-control, fears, obsessions, character, and habits are among the subjects discussed.

HEART DISEASE, BLOOD PRESSURE, AND THE NAUHEIM-SCHOTT TREATMENT. By LOUIS FAUGÈRES BISHOP, A.M., M.D., Clinical Professor of Heart and Circulatory Diseases, Fordham University School of Medicine, New York City; Physician to the Lincoln Hospital; Late Chairman of the Section on Medicine, New York Academy of Medicine; Member of the New York Pathological Society; Alumni Association, St. Luke's Hospital, etc. Third Edition. New York: E. B. Treat & Co., 1909.

THE fact that a third edition of this work has been demanded will cause no surprise to those familiar with the earlier editions, for the author's treatment of his subject, so far as he goes, is clear and satisfactory. The chief faults to be found are that the management of the subject is not sufficiently comprehensive, and that the statements made are not always supported by convincing arguments. The theory that there is a brain center presiding over the tone of peripheral blood-vessels, for example, is insisted upon, but sufficient evidence is not furnished to force its acceptance upon those interested in the problems of the blood-circulation. In describing vasomotor control, also, the author makes no mention, so far as we can find, of the importance of the sympathetic nervous system, but appears to regard this control as exercised entirely by certain cerebral centers. The statement that head noises in elderly people are sometimes due to circulatory disturbances is of interest, and is borne out by the experience of those whose practice has to do with the aged, many of whom complain bitterly of the pulse sounds in the ear. The explanation of these sounds, the author says, would seem to be the circulation of blood through badly filled blood-vessels in the neighborhood of the organ of auditory sensation. Dr. Bishop emphasizes the fact that clinical workers should not yield so much to the laboratory as they are now in the habit of doing, and in this one feels that he is quite right. The description of the Nauheim treatment, as practised in Nauheim itself and as it may be administered, sometimes more satisfactorily, in New York and in the patient's own home, is clear and satisfactory.

DIAGNOSTIQUE ET TRAITEMENT DES MALADIES DU NEZ. Par le Dr. J. GAREL, Médecin honoraire des hôpitaux de Lyon. 145 Figures dans le texte and 4 Planches hors texte. Troisième Édition. Paris: Vigot Frères, Éditeurs, 1910.

THIS, the first of the new year's crop of books on rhinology, covers the usual range found in a simple manual and presents a very fair and complete exposition of the usual topics. The author wisely avoids the discussion of disputed points and confines himself to accepted theories, modified by his own experience which has been an extensive one. The book is printed and illustrated in an attractive form.

DOCTOR RAST. By JAMES OPPENHEIM. Illustrated. New York: Sturgis & Walton Company, 1909.

THIS little book is a clever presentation of a series of episodes taken from the daily life of Dr. Rast, whose character it is the author's purpose to delineate. Dr. Rast lives in the teeming slums of the East Side of New York City, drawn and held there by his love for humanity, and absolutely turns his back against the temptation to flee to a lucrative practice in a pleasant rural district. Dr. Rast has the philosophic habit and sees things socially and religiously. He is a social experimentalist though he lives in the scientific spirit. Dr. Rast defines a doctor as "simply an ordinary man, like Jesus, who lays his hands on the filth of the world's flesh, but lays his heart and soul on bruised hearts and broken souls," and he proceeds to live up to his ideal. The author has succeeded in making the book intensely human and the life in the locality very realistic. The book is a timely reminder that the practice of medicine is something more than a science or a business.

BACTERIOLOGY FOR NURSES. By ISABEL McISAAC, Author of "Primary Technique," "Hygiene for Nurses," "Hygiene for the Use of Public Schools." New York: The Macmillan Company, 1909.

THIS is the latest addition to the list of scientific books for nurses, and it is one of the poorest that we have seen. About the quantity of bacteriology that nurses really need, we have nothing to say just now; but a perusal of this volume convinces us that a knowledge of the English language should be demanded of those who write for pupil nurses. Some of the expressions which we have marked, are: "The nature of the protein substances of bacteria are" (page 14); "the elaborate minutiæ * * * has grown" (page 19); "the presence of bacteria * * * insure" (page 32); "the injection of the poisonous products * * * have caused" (page 80); "the staining and cultivation is" (pages 102 and 105); "the bacillus coli are found" (page 108); "a class of parasites are distributed" (page 155); "the odor or flavor are," and "filtration or boiling are" (both on page 174). Mere typographical errors we pass by. On page 29 the spores of the anthrax bacillus are said to survive drying for ten years or more; on page 150 they retain their vitality for thirty years. On page 30 we are told that "both carbon and nitrogen must be resolved into simpler forms before absorption can take place"; but as both carbon and nitrogen are elementary substances, it would be difficult to resolve them into anything simpler. On the same page, we read "parasites, * * * as the name indicates, exist in living tissues"; but there is nothing in the name to indicate the fact stated. On page 43 we find that diastatic enzymes convert sugar into starch. We have probably given sufficient extracts from this book to show that pupil nurses will be better employed in acquiring the details of practical nursing than in reading this "Bacteriology for Nurses."

The Principles of Pathology. By J. George Adami, M.A., M.D., LL.D., F.R.S.; Professor of Pathology in McGill University and Pathologist to the Royal Victoria Hospital, Montreal; Late Fellow of Jesus College, Cambridge, England; and Albert G. Nicholls, M.A., M.D., D.Sc., F.R.S. (Can.), Assistant Professor of Pathology and Lecturer in Clinical Medicine in McGill University; Out-Patient Physician to the Montreal General Hospital; Assistant Physician and Pathologist to the Western Hospital. Vol. II., Systemic Pathology. With 310 Engravings and 15 Plates. Philadelphia and New York: Lea & Febiger, 1909.

Those who had the pleasure of reading and studying the first volume of this work will welcome its successor and complement which has now been issued. It is written in the same easy, almost colloquial and logical style as the first volume, which makes the reading a real pleasure and lures one on from subject to subject almost as the plot of a well-constructed story. The first volume was by Adami alone, but in the preparation of this one he has had the assistance of Nicholls, his associate at McGill. In reading with the subject of special or systemic pathology the authors have not been content with simply noting the anatomical changes in the various organs occasioned by the disease process, but have included a study of the effects of those changes upon the functions of the organs, a most important subject and of immediate actual value to the practitioner, but one which is usually ignored in treatises on pathology, and left to works on general medicine and surgery. The advantage of treating of this in immediate relation with the anatomical changes is so obvious that it is strange that it should have been so generally omitted by writers on pathology. It marks a tendency away from minute specialism and a recognition of the fact that the science of medicine is a harmonious unit which cannot be separated into unrelated parts without detriment to the whole. The authors have broken the tradition which places anemia, plethora, and other affections of the blood and disturbances in its distribution in the division of General Pathology, arguing very justly that there is no reason why hemal and vascular and not nervous and respiratory disturbances should be treated as portions of the course in General Pathology. This volume on Systemic Pathology opens, therefore, with a section on the cardiovascular system, including the blood, the heart and blood-vessels, the blood-forming organs, and the lymphatic system. Following this is the usual section on the respiratory, alimentary, nervous, urinary, reproductive, ligamentary, muscular, and osseous systems, and the ductless glands.

The publishers' work has been well done, the type is clear, the illustrations are numerous, well executed, and well printed, and the binding is substantial. The book has not the usual fault of those illustrated with half-tones that in the matter of paper the text has been sacrificed to the pictures, and in order that the latter may show well the reader's eyes are tortured with a glare, especially by artificial light, which tempts him to forswear knowledge that must be gained by headaches and lacrymation. The paper here is of a fairly dull finish, yet sufficiently smooth to bring out the pictures, and so the book can be read in any light with comfort. For this the publishers deserve the thanks of the medical public.

Biographic Clinics. Vol. VI. Essays Concerning the Influence of Visual Function, Pathologic and Physiologic, upon the Health of Patients. By George M. Gould, M.D., Formerly Editor of *American Medicine;* Author of Various Medical Dictionaries, "Borderland Studies," "The Meaning and the Method of Life," "Righthandedness," etc. Philadelphia: P. Blakiston's Son & Co., 1909.

This latest, and, as the author tells us in the opening essay, last volume of the interesting series of "Biographic Clinics," resembles those which have preceded it in the character of its contents and in the manner of treatment of the subjects, though the style is, if anything, a little more vitriolic. Dr. Gould is an original thinker, and what he writes is almost always interesting, and he is, moreover, earnest and honest in his advocacy of a great truth, though, like most men of one idea, he exaggerates the importance of his subject and antagonizes those whom he would convert by the extravagance of his assertions. His greatest fault, and the one which has hindered the success of the cause he has at heart, is his inveterate habit of invective and vituperation. He views all his opponents with a moral astigmatism uncorrected by charity, and accuses them all—oculists, internists, neurologists, and surgeons—of greed and criminal extortion if they do not agree with him that the sum and substance of human pathology are founded upon uncorrected eyestrain. He writes like a disappointed man who despairs of converting the medical world to his way of thinking. It is a pity, for it is a great truth he advocates; eyestrain undoubtedly is at the bottom of much physical and mental suffering, and if the cause had been more tactfully presented much more of this suffering would now be finding relief. Now that Dr. Gould has retired from the contest, we may hope that some better poised advocate may take up the cause, and by argument and example, untempered by temper, persuade his fellows to look into the subject of eyestrain without prejudice and in a scientific spirit. When this is done, much for which Dr. Gould has contended will be accepted.

The present volume contains twenty-two essays on subjects connected with eyestrain. Two of them—"biographic clinics"—are on Jonathan Swift, the others on various living subjects. The opening chapter is entitled, "Valediction." In it the author announces that he has laid aside his pen, having given to "the gospel" all the strength and money he could spare, but he hopes and believes that others will take up the task, and that the money and the zeal will be found to train men to prosecute the work. He quotes from the recent writings of many leaders in various branches of medicine to show that the seed he has sown has taken root here and there, and if this were the only essay in the book one who believes that Gould is right, in the main, would be spared the discouragement which is caused by a reading of the other chapters, notably that on "Medical and Ophthalmic Blunders." Several of the chapters, not polemic in character, will be found instructive by the young ophthalmologist in his study of the difficult science of refraction, and a number contain points and hints which can be put to good use in daily practice. There is one chapter which ought not to have been included in any published work. It is a letter from a patient, who gives address and signature, in which the secrets of the consultation room are revealed, to the credit of neither patient nor physician. The writer is evidently an hysterical woman, who confesses to kleptomania, among other faults, and who was cured of her propensity to take what did not belong to her, as well as of vomiting, as it were in the twinkling of an eye, by the fitting of glasses. Suggestion, of course, had no part in the cure! This case is so evidently one of hysteria, accentuated possibly by eyestrain, that its citation will hurt rather than help the argument. The inclusion of the report among Dr. Gould's writings was a blunder—worse, indeed, than a blunder, for it was an offence against ethics and good taste. The chapter mars what is otherwise a most entertaining and readable book, despite the faults of style and method to which we have before alluded.

Causes of Disability as Applied Under Accident and Health Insurance Policies. By Charles Hamilton Harbaugh, M.D., Expert Examiner and Adjuster, Medical Director American Examiners' Association, ex-President American Association of Medical Examiners and Philadelphia Medical Examiners' Association, formerly Demonstrator of Syndesmology in the Jefferson Medical College, Member of the American Medical Association, Philadelphia County Medical Society, etc. Octavo of 650 pages, with 123 half-tones and 15 full-page plates, 11 in colors. Philadelphia: Overbrook Publishing Company, 1909.

This book is designed for the use of insurance and fraternal examiners, general practitioners and students of medicine, attorneys, and corporations. Years of experience have shown the great need that exists among doctors for a book giving information concerning accident and health insurance examinations. The book contains the following chapters: Advantages of making accident, health, and liability insurance examinations; necessary qualifications for a successful insurance examiner; examining for accident insurance companies; policy forms; injuries and diseases of the head and neck caused by accidents and resulting in disability; injuries and dislocations involving the joints and bones of the face; injuries to the neck, including the larynx and trachea; accidental injuries involving the chest, abdomen, and back which result in disability; injuries and diseases of the male sexual organs and surrounding parts; accidents and diseases of the upper extremities; of the lower extremities; illnesses causing disability of the skin; of the brain, and nervous system; of the circulatory system; of the lungs and respiratory system; of the digestive system; of the liver; of the kidneys and bladder; fevers; miscellaneous diseases; disability due to poisons and gases; adjusting claims for disability resulting from accidents or diseases; methods of securing appointment as examiner for insurance companies and when appointed, how to command examinations in competition with other physicians. This book fills a want in this particular field of work.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, December 20, 1909.

THE PRESIDENT, DR. ROBERT T. MORRIS, IN THE CHAIR.

Symposium on the Throat Symptoms of General Diseases, with Therapeutic Suggestions. Syphilis and Allied Conditions.—Dr. HENRY L. SWAIN of New Haven, Conn., read the introductory paper on this subject, in which he confined himself to a consideration of the lesions of the mouth and pharynx, and largely to the question of the diagnosis of syphilis from the diseased conditions which were most readily confounded with it. Given an ulceration in any part of the mouth or throat, what might such a lesion be? It might be an original sore, the primary manifestation of syphilis; it might be a mucous patch; it might be a so-called tertiary lesion, an inherited syphilis, a Vincent's ulceration, an aggravated canker sore, a tuberculous ulceration, a lupus, a so-called noma, a cancer, a postexanthematous or postdiphtheritic ulceration, a pemphigus, a pemphigus-like ulcer following la grippe, a thrush, or a leucoplakia buccalis. It might be any one of these, but the physician, if of an analytic turn of mind, could mentally exclude this or that form of trouble according to the age of the patient, the frequency with which the manifestation occurred, the location in which the lesion most often manifested itself, and the characteristics, number, and other objective appearances. He might use to help him out microscopical examinations of some of the portions and contents of the sores, and, lastly, he was governed by the constitutional symptoms and history. Age, for example, readily excluded some causes, but this rule, however, should not be too rigidly applied. Fortunately, many of these forms of ulceration could immediately be ruled out on account of their great rarity, provided only that the examiner was careful in his consideration of the picture as presented. From the number and location of the ulcerations present something might be deduced: For example, mucous patches occurred all over the mouth; they were frequently symmetrical and were exceedingly rarely present singly. Vincent's ulceration rarely occurred excepting upon the tonsils and adjacent tongue, or gums. The deeper, large ulcerations of syphilis occurred on the tonsils, soft palate, gums, and posterior pharyngeal wall. The gummatous infiltrations occurred largely upon the hard palate, and included sometimes portions of the soft palate, a denudation of bone taking place over the area of the original gummatous deposit, and a sequestrum of considerable size sometimes forming, owing to the interference with the nutrition. Canker sores occurred anywhere in the mouth and cheeks, but rarely upon the tonsils, soft palate, and pharynx. Tuberculosis was rarely, in the speaker's experience, found in the mouth. Chancres of the mouth, outside of the lips, usually affected the tonsils and tongue. Carcinoma, if one excluded the lips, occurred more frequently on the tongue, and epithelioma of the tonsil was not infrequently recorded. Noma, when it appeared, was usually on the cheek. A general stomatitis, when of an aggravated type, or a thrush, might have isolated spots of ulceration in various portions of the cheek, gums, and tongue, but usually it was perfectly clear that the ulcerations were but part of the general manifestation. Leucoplakia occurred upon the tongue and sometimes upon the cheek and gums. There was a distinct form of syphilitic inflammation of the gums which might be the only manifestation found in the mouth. Lupus, when it occurred in the throat in children, as well as hereditary syphilis, was liable to affect the deeper portions of the pharynx and postpharyngeal wall, and they produced the most atrocious scars of any form of ulceration with which he was familiar. The only way that he could differentiate between these two forms of ulcer or the scars that resulted from them was by the use of tuberculin. Dr. Swain then discussed in detail the appearance and characteristics of these various lesions of the mouth and pharynx and cited illustrative cases. In discussing their treatment, he said that if the lesion was syphilitic, a solution of bichloride (1-200 or 1-250) could be applied, and would cause it to heal up rapidly, especially when combined with proper internal treatment. By chance he once applied a 10 per cent. zinc chloride solution to a Vincent's ulceration, and it healed up so promptly and so exquisitely that he had used it ever since, to the exclusion of other remedies. Nothing seemed so good for canker sores as pure sticks of nitrate of silver. In the treatment of gross syphilitic deposits as they appeared in the soft and hard palate, it must, of course, be a cardinal rule to get the greatest possible effect from the antisyphilitic medication in the shortest possible time, so as to limit the defects. The greatest asset which we could have in handling the syphilitic, and the one which was often the hardest to obtain, was the loyal adherence of the patient to the long period of treatment and to any one physician.

Dr. FRANK C. RAYNOR of Brooklyn said that in his part of this discussion he would restrict himself to a few remarks on the diagnosis of the primary sore, and the treatment of syphilis as it affected the throat. Local pain, while not characteristic and of varying degree, was the one symptom that directed attention to the throat, and, while the lesion might be atypical as to appearance and location, we had coexistent constitutional symptoms, not associated with other diseases with which it might be confounded. As the chancre did not make its appearance until some time after infection—two or three weeks, usually—the presence of a general toxemia was apparently evidenced by malaise, slight fever, anemia, and headache, more or less continuous, but worse at night. In the constitutional treatment of syphilis, Dr. Raynor said he relied almost exclusively on the administration of remedies *per os,* as he found this method generally effective, and less objectionable to the patient than inunctions or intramuscular injections, the value of which, however, he did not dispute, and, on occasion, employed. In the earlier stages, as a rule, he used a variation of the "mixed treatment," employing therefore a tablet containing corrosive sublimate, gr. 1/64; potassium iodide, gr. 2; syrup of ferric iodide, minims 5; Donovan's solution, minims 2, and tincture nux vomica, minims 2. This formula was based on an old mixture employed for many years by Dr. Samuel Sherwell. In addition to the antidote, mercury, and to the eliminant, iodine, it contained the tonics iron and nux vomica, and last, but by no means least, arsenic. This he believed to be a very valuable addition, and to it he largely attributed the good results obtained by the employment of relatively small doses. He had never found occasion to use the huge doses of the iodides so often recommended. In the later stages of the disease he usually supplemented the tablets with the mixed iodides in varying amount, rarely going above ten or twenty grains.

Dr. H. ARROWSMITH of Brooklyn, speaking of Vincent's angina, said that American medical literature was particularly devoid of any special reference to this disease, which he believed was much more common that had been generally appreciated, and furthermore, that its possibilities for harm were exceedingly great. Undoubtedly many cases that were observed were classed under some other category. The general supposition that the disease attacked the soft parts alone was erroneous, for cartilage and bone were involved, several fatal cases having been recorded, and a higher mortality would probably follow more general recognition of the disease. The diagnosis was to be made only from smears, as the bacteria could

not be successfully cultivated, which might explain why specimens submitted as probable diphtheria (which Vincent's angina in the early stage very closely resembled) had been returned with a negative report. Treatment was very unsatisfactory.

Tuberculosis: Primary, Buccal, Laryngeal; Lupus.—Dr. Wolff Freudenthal said that a tuberculous lesion, once firmly established in any part of the human organism, could no longer be regarded as a localized disease, but a general one. In what way could a laryngologist assist in the diagnosis of pulmonary tuberculosis? It was certainly a fact that in doubtful cases there were certain signs in the upper respiratory tract which gave us a clue to the presence of pulmonary disease. One of these symptoms, to which the speaker said he had called attention many years ago, was the occurrence of ulceration in the upper part of the pharynx, which was so characteristic that it could not be mistaken for any other type. The only one with which it might possibly be confounded was the tertiary lesion of syphilis, but even from this it was quite distinct. Another distinctive symptom a little lower down in the buccal cavity was an outspoken anemia; this pallor was so marked that it could not be overlooked, and it extended over the hard and the greater part of the soft palate. From that point where the uvula joins the soft palate we had just an opposite condition—a marked congestion of the mucosa extending over both sides, around the pillars and tonsils, while again, further down, the epiglottis showed an anemia. These conditions, of course, were not present in all cases, but when you got such a picture you were inclined to say that you were most likely dealing with a case of pulmonary tuberculosis. Another symptom to which the speaker called attention, which he had found of value in doubtful cases of pulmonary tuberculosis, was the hypertrophy of the lingual tonsil, and that this part should be affected seemed to him to speak in favor of an ingestion tuberculosis rather than an inhalation tuberculosis. As to the therapeutics of pulmonary tuberculosis, Dr. Freudenthal said we were, so to speak, at a standstill; absolutely nothing new had been done either here or abroad since Dettweiler advocated the open-air treatment and Koch introduced his tuberculin. On the other hand, the treatment of tuberculous lesions of the upper air tract had made enormous advances. In former years a patient with a tuberculous lesion of the throat was considered lost, but this was not so now.

Dr. Bryan DeF. Sheedy, in continuing the discussion of this subject, said we had been doing so much of late for tuberculous involvement of the lungs that he believed general practitioners should give the subject of laryngeal tuberculosis more consideration than it had up to this time received. Discussing first the avenues of infection, Dr. Sheedy said we knew that infection of the upper air passages from the bacilli-laden atmosphere was very unusual, and we also knew that primary infection of the larynx in any part, whether from the air, the lymphatic channels, or by reason of mucus containing the bacilli passing over its normal surface was extremely rare. The speaker said he believed that when we had more improved methods for the positive diagnosis of pulmonary tuberculosis, we would find that practically all cases of laryngeal tuberculosis were secondary infections. Few of us would be willing to go on record as making a positive diagnosis of primary laryngeal tuberculosis and adhering to that opinion without some confirmatory evidence, such as we might expect from the microscope or from prolonged observation. The overwhelming majority of cases of laryngeal tuberculosis must be considered as secondary to lung involvement. Discussing the prognosis and treatment of laryngeal infection, the speaker said that the statement of an American observer that tuberculous infection was more virulent and less rare the nearer it located itself to the outer world, he believed to be true. In other words, when we had a tuberculous involvement of the upper breathway, the disease was more rapidly fatal than when located in the larynx, and that pharyngeal involvement generally meant miliary tuberculosis; that the laryngeal infection was always less virulent than the pharyngeal, and that severe laryngeal involvement was generally more surely progressive than lung involvement. In woman, particularly in the prospective mother, the experience of most observers was that a very short period of life remained to the woman who was delivered while suffering from laryngeal tuberculosis. Surgical interference in cases of laryngeal tuberculosis, where there was any marked inroad on the general health due to the lung condition, was contraindicated. The patients who suffered from pain and dyspnea were the ones who usually had a markedly ulcerated condition of the larynx, and these were the cases who derived the greatest possible benefit from local treatment. In the cases without ulceration, which generally meant without pain, we used soothing applications, and only when the case was positively tuberculous, with apparently no lung involvement, did we think of operative procedure; while the cases of ulceration we put under active local medication, and nearly all could be made comfortable and freed from pain. His own practice was to cleanse the ulcerated surface with a warm alkaline wash through the means of a cotton wound applicator, then cocainize with a 10 to 20 per cent. solution of cocaine, and afterwards apply lactic acid directly to the part through a Killian tongue depressor, beginning with a 25 per cent. solution, and running it up in the course of a week's time to full strength. He had also used a solution containing lactic acid, 50 per cent.; formalin, 7 per cent., and carbolic acid, 10 per cent., with fairly satisfactory results. The ulceration in most cases occurred between the arytenoids, but many exceptions to this were constantly observed. Involvement of the epiglottis had occurred in a few cases that came under his observation, and in these the removal of the epiglottis seemed to be a beneficial procedure.

Exanthemata: Measles (Simple, German), Scarlet Fever, Thrush in Children.—Dr. Francis J. Quinlan, in discussing this phase of the subject, said that affections of the upper respiratory tract occurring in the course of the exanthemata could best be considered and treated according to their different degrees of intensity. Thrush, for example, was generally regarded as a very light disease, but there were times when it assumed alarming aspects, producing symptoms of suffocation which might render tracheotomy or intubation imperative. In measles we had the characteristic catarrhal inflammation of the entire upper respiratory tract, either preceded or accompanied by Koplik's sign. In the large proportion of cases, this inflammation did not go beyond the catarrhal stage, but in some instances the constant coughing produced mechanical ulcerations and suffocative spasm, and even gangrene and edema of the glottis had been reported. Infection of the antrum and other accessory sinuses might also occur. In scarlet fever we had the characteristic strawberry tongue and injection of the fauces, varying in degree from a slight redness to an intense inflammation, with swelling and induration of the soft parts and the formation of a pseudomembrane, with possible mechanical obstruction to deglutition and respiration. Extension of the infection to the Eustachian tubes was a not infrequent complication, and gangrene of the tissues was at times observed. In the treatment of these inflammatory conditions of the upper respiratory tract accompanying the acute exanthemata, in addition to systemic remedies, the speaker advocated the use of a mild cleansing agent, preferably Dobell's solution. In threatened edema of the glottis as well as in all acute and subacute conditions of the larynx, he favored the use of a spray of a solution of silver nitrate, which he felt as-

sured, if employed in time, would prevent the necessity of intubation in many cases. He emphasized the importance of a laryngoscopic examination by the general practitioner as a more routine procedure for the more thorough examination of the throat and its more careful treatment, and finally, as a prophylactic measure, he urged the early removal of obstructive lesions of the nasopharyngeal tract, particularly adenoids and tonsils.

Typhoid Fever: Mouth, Throat, Laryngeal Crises.—Dr. Lewis A. Coffin, confining his remarks to the laryngeal complications of typhoid fever, said that while such conditions were so rare in the experience of many practitioners that they might seem scarcely to merit discussion, yet in various parts of the country where there are frequent and severe epidemics of typhoid from laryngeal complications, they are not infrequent and often serious. In a paper by Drs. Jackson and Day of Pittsburg which they read some years ago before the American Laryngological, Otological, and Rhinological Association, they reported two cases of severe perichondrial inflammation of the larynx complicating typhoid fever, and subsequently took up the systematic study of the subject in one of the hospitals of Pittsburg. Of 360 cases that were carefully watched throughout the course of the disease, 227 showed lesions in the larynx. They were able to divide these cases into three classes: 1st—A subacute laryngitis; 2d—Larnygitis with ulceration of the mucous membrane. In the third type the ulcerations were more severe, involving the cartilages and pericartilaginous tissues, with or without necrosis. Dr. Gibb of Philadelphia, who had also enjoyed unusual opportunities for studying the disease, had confirmed the findings of Drs. Jackson and Day, and also spoke of a paralytic type, in which there was paralysis of the larynx. Personally, Dr. Coffin said, he had never observed these conditions, but he recalled one case, seen in consultation, in which there was a confluent ulceration of the palate, with extensive inflammation and edema of the uvula. As to the etiology of these conditions, they were doubtless the result of the typhoid toxemia. As predisposing factors, Jackson mentioned the dorsal decubitus, lessened cough reflex, and throat trouble prior to the onset of the typhoid fever. He was also inclined to believe that draughts and perhaps hydrotherapy—especially the ice-pack—might provoke laryngeal complications. The milder cases were best treated on the expectant plan, with inhalations of steam, medicated or otherwise. In the severer cases, with edema, intubation was useless; tracheotomy was the only relief.

Dr. Nathan B. Van Etten said the tongue told many truthful tales in typhoid. Progressively, through the usual course of the disease, it told the story of expected events in ordinary sequence. It told of danger and amelioration; it told of neglect, and it reflected the labor of the careful and conscientious nurse. At the onset, the tongue was covered with a white fur, which gradually thickened, but was still moist. The edges might be clear red, with the white fur covering the tongue centrally. The cause of the coating was an overgrowth of the epithelium of the mucous membrane, but it was not fully understood. The thick whitish coat was made up of microorganisms, degenerated epithelial cells, and particles of food. In the second week, the tongue was dry and covered by brownish fur; later, dryness of the mucous membrane of the entire mouth increased, the center of the tongue might be a deep brown, or sometimes there was a black, dry fur, which might form crusts and fissures. The mouth was dry from diminished secretion of saliva, from mouth breathing, and from diminished movements of the tongue. Small fissures were common, and some bleeding might come from them. The movements of the tongue were characteristic. When protruded, it was tremulous, and in the later stages, in severe cases, there was hesitation; the tongue was protruded, and the patient, apparently forgetful, failed to withdraw it. In the third week the tongue might be shriveled, stiff, raw, and fissured, and the lips might be dry and cracked. There might be sordes on the gums, teeth, and lips. The pharynx shared in the general dryness of the mouth, and might be covered with a very tough, sticky mucus, which made drinking difficult and which the patient was unable to cough up and from which he suffered great discomfort. The uvula, tonsils, and pharynx were often ulcerated, and in cultures from these ulcers, typhoid bacilli had often been obtained. The frequent finding of the bacilli in the sputum indicated the necessity of the destruction of all mouth secretions as sources of infection. In the fourth week the tongue became moist and began to clear at the edges. If the mouth be not kept clean in typhoid fever, complicating secondary lesions in organs more or less remote from the mouth might develop with unpleasant and serious symptoms. Parotitis was not uncommon; it was usually unilateral, but might be bilateral. Suppurative otitis media was a rarer complication. Fungi might appear on the tongue and elsewhere on the buccal membrane in the form of thick white patches; the fresh patches were glistening white; the older patches were dirty gray. Lingual ulcers might occur, and were usually benign. By giving water very freely internally, and regular local attention to the mouth, and by keeping the nose clear, so as to limit mouth-breathing measurably, the tongue might remain moist and only lightly coated, and the lips might be nearly normal. In a recent series of thirteen cases of carefully nursed typhoid fever seen in private practice the speaker said he had had almost no unpleasant mouth symptoms.

Dr. Robert C. Myles said that Vincent's angina seemed to occur in waves, and in his own experience it was much more frequent in some years than in others. In the treatment of this condition, the germs, which were often deeply imbedded in the tonsillar crypts, must be destroyed; otherwise there was strangulation of the circulation, and sloughing of the parts occurred. In spite of the profound depression and the destruction of the tissues associated with Vincent's angina, recovery was the rule. In dealing with tuberculous lesions of the tonsil and soft palate, the speaker emphasized the importance of thorough excision, followed by the use of the cautery. In the milder forms of tuberculosis of the larynx and epiglottis, the outlook was much more hopeful than formerly, but when once the disease had invaded the arytenoids or deeper structures, it usually terminated fatally. In measles and scarlatina in children who had had their tonsils and adenoids removed, the throat symptoms were usually much less aggravated than in those who had large tonsils and adenoids. Our greatest hope in the treatment of all these infectious diseases was in the discovery of a serum treatment.

The discussion was then closed by Drs. Swain and Quinlan.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 4, 1910.

Dr. Charles N. Dowd in the Chair.

A Case of Fracture of the Pelvis with Extraperitoneal Laceration of the Bladder.—Dr. J. F. McCarthy presented a boy, twelve years old, who was admitted to Bellevue Hospital July 27, 1908. One-half an hour before admission he was caught between the wheel of an ice truck and a platform, the trochanter apparently having been engaged. The boy stated that five minutes before admission he voided urine, so that the possibility of a full bladder played no part in the injury. He presented the usual phenomena accompanying a severe injury, some blood appearing at the meatus. The exploration of

the pelvic girdle was negative, as was also the rectal examination. The catheter returned a small amount of blood-stained urine after which about six ounces of fluid was introduced, all of which reappeared. The catheter was retained in the bladder for twenty-four hours; it was then expelled and it was impossible to reintroduce it. At this time there was no impairment in the various movements of the extremities. A suprapubic incision revealed a large amount of fluid in the prevesical space, and a collapsed bladder containing blood clots. A complete laceration about one and a quarter inches long just above and to the left of the vesical orifice was found. On the same side of this organ exteriorly a large splinter of bone with a number of smaller ones could easily be felt, the projecting end of one large splinter being about two inches from the bladder. A perineal incision was made and the bone area was drained through this wound. Suprapubic bladder drainage was instituted for two days, and then perineal drainage; from this time the case progressed uneventfully. It was now one and a half years since the wounds closed and the condition was excellent. At the time of the boy's admission he also presented the very unusual condition of the perineal type of maldescent of the testes. The conclusions to be drawn from this case were as follows: (1) That the so-called capacity test of the bladder integrity was not tenable, and might even be grossly misleading. (2) That here was a case of true extraperitoneal laceration of the bladder and not a rupture so-called. (3) It clearly demonstrated the experiments of Kusmin that lateral pressure might bring about injuries similar to a force acting in an anteroposterior direction. The question as to the part played in the mechanism of the injury and by the developmental state of the pelvic girth at this age also added to the interest of this rather unusual case.

Resection of Jaw for Ankylosis.—Dr. Charles E. Farr presented a man, thirty-two years old, who, many years ago, had an abscess of the jaw, with an osteomyelitis, resulting in an ankylosed jaw. This condition existed for twenty-eight years, during which time he was unable to take solid food. Dr. Farr saw him ten months ago when he made a short transverse incision, displaced Steno's duct and the facial nerve, split the fibres of the masseter muscle and thus came down upon the ramus of the jaw. He excised the condyle, but even then he got no motion. When he cut off the coronoid process, however, he obtained some motion. He decided that much of the ankylosis was due to lack of use of the jaw. The wound healed fairly well. The patient was now able to open his mouth one inch and could take and chew solid food. Technically the operation was an easy one.

Perforated Gastric Ulcer.—Dr. Hermann Fischer presented this case. The father died of cancer of the stomach, otherwise the family history was negative. Two days before entering the hospital the patient complained of pain in the upper part of the abdomen and chest; he had considerable dyspnea. At the end of twenty-four hours the pain became very severe and was most acutely felt in the right iliac region over the appendix. Soon the pain extended over almost the entire right side of the abdomen; he complained of shooting pains which traveled up to the neck, affecting chiefly the right side, but at times involving both sides. The pain was not referred at any time to the back or the right shoulder. Twenty-four hours after the onset of his illness, the most striking symptom was the dyspnea. His pulse was between 85 and 90, regular and of good quality. The entire right side of the abdomen was very tender and there was marked rigidity of the abdominal muscles on that side. The point of greatest tenderness was over McBurney's point. He had never had any symptoms referable to the stomach. No tumor was felt and there were no signs of fluid. A diagnosis of an acute cholecystitis or an acute appendicitis was made and the patient was advised to go to the hospital. A few hours after his admission the point of greatest tenderness changed to the region of the gall-bladder, and Dr. Fischer was convinced that he had to deal with an acute cholecystitis. The morning following his admission he operated. Upon opening the abdomen a fibrinous exudate was found along the lower border of the liver, as well as on the upper surface of the right lobe; it also covered the omentum which was adherent to the stomach and to the lower surface of the liver. This concealed the gall-bladder and its ducts. On separating these adhesions he found, to his surprise, that the gall-bladder was entirely normal and not at all responsible for the state of affairs. When separating these adhesions to the pylorus he suddenly heard the noise of escaping gas; he then found a small piece of omentum which, after being removed, revealed a pin-hole perforation of the stomach, close to the pylorus. The walls of the stomach in the immediate neighborhood were succulent and injected, but not markedly infiltrated, so that the closure of the opening was readily effected. The patient made an uneventful recovery. This case seemed to be of interest from several different aspects. (1) The patient had never had any symptoms that would make one think of the possible presence of an ulcer of the stomach. (2) They probably had to deal with an acute ulcer of some toxic origin. (3) The perforation occurred in the morning when the stomach was empty and the opening so small that only a fine probe could be admitted. The escape of gastric contents was thus minimal and the patient had excellent chances for recovery.

Finney's Operation for Perforated Gastric Ulcer.—Dr. Aspinwell Judd presented a patient, twenty-four years old, whose father died of cancer of the stomach. He had had symptoms of gastric ulcer, including hemorrhage, as well as pyloric stenosis and had lost twenty-six pounds in weight in two years. He had been on a milk diet for several months. The gastric motility was found to be good, as shown by the use of apple sauce and bismuth and the *x*-ray. He decided to operate and made the classical incision for gastroenterostomy. He found the stomach, the gall-bladder, omentum, and liver matted together. Upon separating the adhesions he found that the omentum was closing a gastric ulcer of some size. At first he thought it advisable to do a posterior gastroenterostomy, on account of the number and extent of the adhesions, but finally decided upon doing a gastroduodenostomy, or Finney's operation. In order to prevent the formation of many adhesions, aristol was freely used. Since the operation the patient had gained twenty-eight pounds in weight. The pylorus as shown by bismuth and *x*-ray was on a proper low level and the function of the stomach was perfect. As in all his posterior gastroenterostomy operations, the patient was sitting up on the fifth or sixth day, the wound thoroughly protected by means of broad bands of adhesive plaster.

Inoperable Endothelioma of the Colon.—Dr. Judd presented a patient who was seen in Dr. Robert T. Morris' service one year ago last October. He had a tremendous mass of irregular outline as large as a child's head, involving the transverse colon and glands and omentum, easily palpable. Everything seemed to be so involved in the growth that it seemed possible to do nothing except an anastomosis. A section of the mass was sent to the laboratory, and it was reported that the growth was an endothelioma. The patient was very much emaciated and cachectic when he came to operation. During the year following the operation he gained fifty five pounds in weight and the mass disappeared under the influence of the *x*-ray adminstered twice a week, using a very high pressure tube. However, the tumor again be-

gan to grow six months after stopping treatment. This demonstrated that almost all cases of sarcoma and endothelioma recur after a time, even though *x*-rayed. In the use of the *x*-ray it was noted that these growths disappeared as kindly under the second administration as under the first. In these cases there was an increase in the fibrous elements. Since recommencing the *x*-ray, the mass had begun to shrink and was now the size of a lemon Otherwise he was in perfect health, with hemoglobin 90 per cent.

Femoral and Inguinal Hernia on Same Side in the Male.—Dr. JUDD also presented this patient. He found only three similar cases in the literature. The operation for radical relief involved no special difficulty and modified Bassini incision being made and classical inguinal and femoral operations being done through the same wound.

Intestinal Obstruction, Resection, and Anastomosis of the Sigmoid in Three Stages.—Dr. JOHN DOUGLAS reported this case. The patient was a young man, twenty years old, who was admitted to Bellevue Hospital with a history of diarrhea, with occasional blood and mucus in the stools for the previous six months. Two days before admission he had acute abdominal pain with vomiting, distention, and constipation. On examination it was found that the abdomen was markedly distended, but there was no local point of tenderness, rigidity, nor elevation of temperature. The pulse was rapid. Repeated enemas failed to cause free bowel action, but a small amount of feces and gas was passed at first. The rectal tube could not be passed more than fourteen or fifteen inches. This latter fact and the evident distension of the colon located the obstruction in the sigmoid, and the previous history of diarrhea, with occasional blood and mucus in the stools, indicated a constriction following an ulcerative condition. A median incision revealed a mass about the size of a walnut in the middle of the sigmoid, and very adherent to the iliac fossa. The intestine above was greatly distended, while below it was collapsed. The sigmoid was freed but could not be brought out of the abdomen without ligating about an inch of the mesosigmoid just below the tumor. The loop of the sigmoid with the tumor at its apex was then lifted up, until the tumor portion was above the level of the skin. The peritoneum of the distended portion above and the collapsed portion of the sigmoid below the tumor were sutured together with catgut along their long axis for a distance of two inches to form a spur after resection of the tumor. The loop of sigmoid, about one inch below the tumor, was then sutured to the peritoneum and the wound was partly closed. A rubber tube was then fastened into the distended intestine above the tumor for the drainage of feces. Thirty-six hours later the tumor was removed without anesthesia. The pathological examination showed the tumor to be inflammatory tissue. The wound became infected from the fecal discharge, but was cleaned up when the spur was cut away by the application of an abdominal clamp left in place until it cut through. The fecal fistula failing to close spontaneously, a general anesthetic was administered and the intestine freed from the abdominal wall and closed by suture. The wound was then closed with a small rubber tissue drain. The case was presented to illustrate the advantage of this method, particularly in acute obstruction in the large intestine, over immediate resection and anastomosis, as the great distension above the obstruction would have made immediate anastomosis difficult and the result doubtful.

Modified Technique for the Combined Operation of Extirpation of the Rectum.—Dr. JAMES P. TUTTLE read this paper. He said that without retracting anything he had heretofore said in favor of the perineal operation for extirpation of the rectum, he wished to state his concurrence in the universal opinion of surgeons that theoretically the combined operation was the operation of choice for the extirpation of the rectum in any condition requiring the removal of more than the lower four or five inches of this organ. Its hitherto high mortality, and the fact that many operators had made the artificial anus a necessary accompaniment of this operation were the only arguments against it. That the latter objection was no longer tenable was shown by the recent writings of Lusk, Hartman, and many others, together with his own report two years ago. The high mortality rate was steadily decreasing, until to-day it was less than that of the perineal operation ten years ago. For tumors where more than four inches of the rectum were to be amputated, the combined method was to be preferred, for the following reasons: (1) It afforded an opportunity to examine the abdominal organs, the glands, and the peritoneum with regard to metastasis. If these existed extirpation was not justifiable, and only a palliative operation, such as curettage or the formation of an artificial anus, should be employed. (2) It enabled one to ascertain how high the growth or stricture extended, and to determine the length of the mesosigmoid at divers points and to select a segment with a good blood supply that could be brought down to the anus without tension. (3) It enabled one to tie the superior hemorrhoidal artery at a point above the anastomosis with the sigmoidal artery, and thus to preserve a good blood supply to the rectum, as had so happily been described by Hartman. (4) It enabled one to clean out all the glands in the intestinal iliac angle, and from there down more perfectly than by the perineal method. (5) By it one could cover up denuded surfaces, and close the peritoneal cavity before opening the bowel. (6) It enabled one to retreat and resort to an artificial anus if the conditions did not warrant total extirpation, or if the length of the sigmoid did not permit the fecal exit to be restored to the anus. The methods employed until recently consisted in selecting a point a short distance below the tumor, tying off the blood vessels *en masse* as one loosened the gut from its attachment to the sacrum regardless of their anastomotic relations; this course had failed simply because of the insufficient and indefinite blood supply to the proximal end of the gut, and to the large denuded surfaces left in the peritoneal cavity after such an extirpation. The technique which Dr. Tuttle had employed for the last three years to avoid this objection was described in detail by him. It differed from that lately published by Lusk in the treatment of the peritoneum, the restoration of the mesosigmoid, in the blood vessels tied, and in the treatment of the ends. It differed from that of Hartman in the same respects except as to the ligation of the blood vessels; in this they followed the same lines. The objections to the combined method were: (1) Its higher mortality, this was decreasing as the technique and dexterity in its performance increased; in the last three years he and Dr. Lynch had done several of these operations, with but one death, and not a single case of incontinence of feces. (2) The objectionable artificial anus so long advised in this method and by so many surgeons as making the operation more radical and safer. It did neither and was rarely advisable not to say necessary. (3) The great amount of gut sacrificed in bringing the intestine down to the anal aperture. There was no more gut lost in this method than there was put out of commission by an artificial anus; moreover, the amount of the sigmoid removed did not seem to add much to the gravity of the operation so long as the proximal circulation was intact. (4) The danger of peritoneal infection. This ought not to be more than in other abdominal operations, for the intestine was not opened until the peritoneal cavity was closed off, and when it was opened it was outside of the body and of the field of operation.

Report of a Series of Cases of Surgery Upon the Large Intestines, with Some General Considerations.—Dr. JOHN F. ERDMANN reported twenty-one cases of surgery of the large intestine irrespective of malignancy, and included eight cases of upper sigmoid malignancy reported previously; these latter were reported in order to enable him fully to consider the operative technique in lower colonic or upper sigmoid cases, using the term upper sigmoid in contradistinction to what they were now pleased to call the lower sigmoid, and formerly the intraperitoneal rectum. Among these cases was one of megacolon (Hirschsprung's disease) occurring in a boy eight years old in which was done a complete excision of the colon and upper sigmoid. There were eight cases involving the sigmoid, one of tuberculous ulceration and infiltration of the cecum with a permanent sinus following an exploration for an appendix; there was one case of excision of the cecum for an old infiltrating sinus of nine years standing, following a spontaneous rupture of an appendicular abscess; there were six cases of carcinoma of the cecum, three of which were excised with two deaths, and three in which enterosigmoidostomy was done with one death; there was one case of general colonic malignancy in a boy of seventeen years, one case of carcinoma of the descending colon and sigmoid in a female eighty-five years old, and one case of colloid carcinoma of the terminal three inches of the descending colon. The earliest symptoms observed were borborygmus, cramps, diarrhea alternating with constipation, a feeling of incomplete emptying of the bowels, the discharge of mucus, blood, and pus, singly or combined, localization of the pain by the patient, or a painful spot on pressure, and finally the localization of the tumor, movable or not, depending upon the section of the colon that was involved. In some cases proctoscopic evidences were obtained. The operative procedure resolved itself into resection with anastomosis, or short circuiting. While the latter was not curative, it should be considered in those cases where the mortality risk was a great factor from a family provider's standpoint. In excising the cecum and sigmoid one should remember their association with the peritoneum. In excising growths of the transverse colon and the hepatic and splenic flexures one should search for the glands in the transverse mesocolon and in the pancreatic area. The removal of any part or all of the colon was easily accomplished if one bore in mind the fact that the outer fold or plate of the peritoneum covering the colon was the hold-fast, and contained no blood vessels; whereas the inner or mesial plate contained the vessels and lymph channels, all of which tended to the median line. Dr. Erdmann said he favored the side to side isoperistaltic anastomosis more than the direct suture, having always felt that his field was kept more sterile. The resection cases were better handled in cases of obstruction in the two stage procedure. Removal of the cecum was done three times for carcinoma, once for tuberculous ulcer and infiltration, and once for an old sinus; of these five cases of excision two died. Dr. Erdmann then reported some case histories.

Dr. FREDERIC KAMMERER said that the statistics offered by Dr. Tuttle were very interesting indeed, because he had not believed the combined operation could be done without a large mortality; that had been his own experience with the operation and, he ventured to believe, the experience of most operators. In cases of cancer of the rectum he had given up resections because he found that invariably in time a stricture of greater or less degree would develop at the point of resection, and near the latter recurrences would frequently appear. For this reason he now did an amputation of the bowel in all cases, after a permanent inguinal anus had been established. A well-established inguinal anus in his opinion was preferable to an anus at the normal site with only partial control. An important point in this connection was the change which took place in a large ulcerating cancer after an inguinal anus had been made. The tumor often decreased to almost half its original size and became more movable, and its removal was then a much more simple process. It had, furthermore, not been his experience that an inguinal anus at the highest available point of the sigmoid ever proved a hindrance to downward traction of the growth when it was attacked by the secral route. Besides, with a permanent inguinal anus, it was unnecessary to draw the upper end of the bowel down to the site of the original anus after amputation. It was sufficient to close it and to fasten it extraperitoneally at the incision into Douglas's pouch, allowing the large wound cavity to heel in part by granulation. As recurrences most always appeared in the bowel, it was of the utmost importance to remove the growth radically in the first instance and, therefore, in trying to save the lower end of the rectum, i. e., the sphincter, the temptation to be less radical than necessary was great, more especially as most cancers were situated in the ampullary portion of the rectum. To establish a permanent inguinal anus and to remove the growth two weeks later was no doubt a less brilliant procedure than the combined operation in one sitting, but, even in very large ulcerating growths, it was eminently safe and was followed by a very low mortality, indeed.

Dr. GEORGE WOOLSEY said that in several cases that he had had the making of an inguinal artificial anus was necessary. For some time he had given up doing a resection. When one brought the bowel down to the anus after doing an excision, sloughing might occur in the terminal inch or so, from interference with the circulation, due to too great tension or improper division of the vessels. Therefore in both these particulars the point in regard to the circulation brought out by Dr. Tuttle, and the bringing down of the sigmoid loop, was a matter of great importance. Dr. Erdmann spoke of the necessity of doing the operation in two stages, where there was a complete obstruction; Dr. Woolsey went further and believed that when the obstruction was not complete and the oral segment was much distended the two-stage operation was the wiser course to follow as he had learned from experience.

Dr. SAMUEL G. GANT believed that the results in Dr. Tuttle's cases could not be improved upon. The pocket found in the rectum in the case reported was nothing more than a thickened rectal valve. Many modifications of Kraske's method had been made; in fact, no one ever performed it as originally described, and probably all surgeons were discarding the Kraske method for the perineal or combined operation. Annular stricture was a commoner occurrence and was usually preceded by a posterior fistula. When possible the ideal operation was the abdominal, doing all the work from above, but when this was not possible it should be combined with perineal proctectomy. When the work was begun from above, metastases in other organs could be determined, the proper vessels could be ligated, all glands could be removed, the bowel could be mobilized to the desired extent, and the work could be performed more aseptically when the incision started from above.

Dr. JOSEPH WIENER said that the work done by Dr. Tuttle in extirpation of the rectum was in a large measure new. There was one point, however, that had not been brought out, that in these cases the question was not an anatomical but a surgical one. He asked if the final results obtained were as good as could be gotten. Would the patients reported by Dr. Tuttle be free of the disease four or five years hence? He believed not. Questions pertaining to the saving of the sphincter were important; personally he had seldom seen a sphincter following the amputation of the rectum that was worth a great deal. Other surgeons had perfectly satisfactory sphincter muscles

following this operation, but Dr. Wiener said he had not had. He believed the questions that confronted them in extirpation of the rectum were rather surgical ones and not anatomical. He did not believe in resections in cases of carcinoma of the rectum, but in amputation.

Dr. William C. Lusk said that following operations for the removal of rectal cancer, recurrence was sometimes attributed in literature to implantation metastases, so that one should cut widely around the diseased area. Dr. Tuttle was to be congratulated on having saved so many sphincters. Dr. Tuttle spoke of the combined operation for high situated cancers only, but Dr. Lusk thought that this operation was quite as applicable for high amputation in low seated cancers, since the lymphatics from the anus and lower rectum followed upward the course of the superior hemorrhoidal vessels. He believed in taking the abdominal route also because, by employing Giordano's technique of ligaturing the internal iliac arteries, as well as the Mayo's technique of ligaturing the sacra media artery, the hemorrhage was more readily controlled. The tendency to stricture could be lessened by the careful application of the mucous edges in uniting the bowel ends. The Maunsell procedure of prolapsing through the sphincters the portion of the bowel containing the tumor, and then resecting the gut outside the anus, was regarded in literature to be applicable only to cases of small tumors.

Dr. Albert A. Berg thought that the report of eleven cases of extirpation of the rectum for carcinoma without a mortality was wonderful. He had had experience with but five cases in which the combined operation was employed; three of these died, two the result of operative shock, and the third from hemorrhage from the internal pudic artery during the third week. What impressed him most in these cases was the tremendous shock that resulted.

College of Physicians of Philadelphia.

At a stated meeting, held February 2, Drs. John M. Swan and John J. Gilbride presented a communication entitled "A Clinical Study of the Cammidge Reaction." They reported the results of examination of the urine from a large variety of cases and they found the Cammidge reaction present when evidence of pancreatic disease was wanting as well as when it was present. Accordingly they came to the conclusion that the reaction was due to the presence of certain substances in the urine resulting from derangement in the function of the pancreas, whether induced by disease of this viscus or more remote disturbance. They had succeeded in obtaining the reaction with urine to which maltose had been added in minute amount, although previously it had been absent. Drs. E. J. Beardsley, Samuel Rhoads, and J. Shelley Saurman presented a communication entitled "Prompt Symptomatic Relief from Wiring in Aortic Aneurysm." They demonstrated a colored man on whom the operation had been performed and referred to a second patient on whom the operation had been performed a second time. The operation is applicable to sacculated aneurysms not otherwise operable, and its results can be looked upon only as palliative, inasmuch as the conditions underlying the morbid formation cause weakness in other portions of the vessel wall and eventually a fatal issue. A hollow needle of platinum or gold is introduced into the aneurysm and through the lumen fine drawn gold wire of varying length is passed. After as much wire has been introduced as will readily be received, the free extremity is connected with the positive pole of a galvanic battery and the negative with a conducting plate applied to back or in some indifferent situation. The current is gradually increased up to 60 or 70 milliampères, the entire treatment occupying from thirty to sixty minutes. Soon after the current begins to pass the pulsation diminishes and the pain subsides, and dyspnea when present likewise improves. The relief thus afforded may persist for many weeks or months, or even for years, and death as a rule results from another lesion or some other condition. Dr. William G. Spiller presented a communication entitled "Tumors of the Brain and Spinal Cord, Especially in Relation to Surgical Intervention," illustrated by lantern slides. He pointed out the need for early operation, diagnosis being desirable to this end prior to the development of general symptoms. Not much is to be expected in the treatment of infiltrating growths, but there are quite a number considered as fibromata or endotheliomata, usually originating from the dura that do not infiltrate, and if in accessible situations are readily shelled out. Tumors of the pituitary body often grow slowly and attain considerable proportions before giving rise to marked symptoms. At times the only symptom may be bilateral temporal hemianopsia from pressure on the optic chiasm. Tumors of the base are in general more difficult of removal than tumors of the convexity. Tumors of the cord, particularly in the cervical or thoracic region, offer better chances of removal than tumors of the cauda equina. Dr. Alfred Stengel presented a communication entitled "Acute Pulmonary Edema in Cardiac Disease and Its Treatment." He pointed out that edema of the lungs might result as the terminal stage of acute or chronic pulmonary disease, in consequence of failure of cardiac compensation, as a manifestation of acute infection, and without apparent cause. He dwelt especially upon the last form and he recited a group of illustrative cases. The disorder sets in with great suddenness and usually without premonition. The pulse is small and feeble, respiration is labored and shallow, and rapid and numerous bubbling râles are audible over all parts of the chest. The patient may be intensely cyanotic. From the mouth there pour large amounts, up to liters, of blood-stained serum. The patient may succumb in the initial attack, although commonly attacks recur at varying intervals, sometimes over long periods of time. Speedy relief is afforded by hypodermic injection of morphine and atropine in moderate dosage. The nature of the disorder has not been established, although it has been thought to be toxic and vasomotor. Dr. John K. Mitchell announced on behalf of Dr. S. Weir Mitchell that the college had received an unconditional gift of $75,000 for the purposes of the college. Dr. Mitchell announced also the contemplated gift of $5,000 by Dr. R. C. Cleeman. The president announced a gift of $5,000 from Dr. Francis X. Dercum, the income of which is to be devoted to the purchase of books on neurology. A proposition for the lease of the old building of the college was received with approval.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Wisconsin Board of Medical Examiners.

January, 1910.

ANATOMY.

1. Name the bones of the head (including the facial).
2. About how many bones are there in the human body?
3. Name each cranial nerve and give its foramen of exit.
4. Describe the spinal nerves.
5. Describe the eyeball.
6. What are the lymphatics?
7. Describe the aorta.
8. Describe the ossicles of the tympanum.

PEDIATRICS.

1. Give symptoms and treatment of intussusception.

2. Give the symptomatology and treatment of hereditary syphilis.
3. Give etiology and treatment of enuresis.
4. Give synonyms, symptoms, and treatment of membranous laryngitis.

PATHOLOGY, HISTOLOGY, BACTERIOLOGY.

1. Define degeneration. Give causes of fatty and amyloid degeneration.
2. Name types of infarcts. Give description of one type.
3. Differentiate transudate and exudate.
4. Give classification of inflammations, and describe one form.
5. Give pathology of atrophic cirrhosis of liver.
6. Give pathology of parenchymatous nephritis in detail.
7. (*a*) Name the tumors of connective tissue origin. (*b*) What determines the malignancy of tumors?
8. What are the causes of arteriosclerosis? Give pathological histology.
9. Name the diseases due to bacteria. How are these diseases communicated?
10. (*a*) Give method of staining the tubercle bacillus. (*b*) Give method of making a Widal reaction.
11. Differentiate the mucosa of the gastrointestinal tract from mouth to anus.
12. Describe blood-supply of liver in detail.

PRINCIPLES AND PRACTICE.

1. Name four organic heart lesions and give the physical signs in two of them.
2. Describe a typical case of typhoid fever.
3. Give the diagnosis of acute lobar pneumonia. Give the treatment of first stage.
4. Give diagnosis of entrocolitis.
5. Give diagnosis and treatment of round ulcer of the stomach.
6. What is amyloid liver? Give diagnosis.
7. Give etiology and diagnosis of arteriosclerosis.

MATERIA MEDICA AND THERAPEUTICS.

1. Name six antiseptics in the order of their power to destroy bacteria.
2. What are the physiological actions and therapeutical uses of arsenic?
3. What anthelmintics are used against the different intestinal parasites respectively?
4. Name five preparations of mercury, with the doses of each.
5. Give the physiological actions of strychnine in poisonous doses, and tell why it destroys life.
6. How would you treat a case of strychnine poisoning?
7. Name six preparations of iron, with the doses of each.

OBSTETRICS.

1. Give the physiology of pregnancy.
2. Give hygiene of pregnancy.
3. Explain the mechanism of labor.
4. Give etiology and treatment of hyperemesis gravidarum.
5. Explain the reasons for the rarity of conception in a prolapsed uterus. If pregnancy does occur in complete prolapse, what is the result?
6. Give diagnosis and treatment of hydatid mole during pregnancy.
7. Give etiology and symptomatology of puerperal eclampsia.
8. Name the causes and give treatment for postpartum hemorrhage.

GYNECOLOGY.

1. Give the pathology of menstruation.
2. State cause and treatment of sterility.
3. Give symptoms, course, and diagnosis of metritis.
4. What are the indications for curettage of the uterine cavity. Describe method of procedure and dangers to be avoided.

NEUROLOGY, DIETETICS, MEDICAL JURISPRUDENCE.

1. (*a*) What is the structural and functional unit of the nervous system? (*b*) Give brief description of same. (*c*) What area of the cord is affected in acute anterior poliomyelitis?
2. (*a*) Describe briefly the spinal cord and name from within out its three protective membranes. (*b*) At what level of the spine does the cord terminate? (*c*) In locomotor ataxia, where is the primary degeneration?
3. (*a*) Give names of the seventh, eighth, tenth, and twelfth pairs of cranial nerves. (*b*) Give function and distribution of any two mentioned. (*c*) Locate the Gasserian ganglion.
4. (*a*) Give origin, course, and distribution of the great sciatic nerve. (*b*) What are the names of the two large branches into which it divides? (*c*) At about what point does the division take place?
5. (*a*) Name the nerves which, under normal circumstances, control the action of the heart. (*b*) Explain how these nerves differ in their function.
6. Differentiate between criminal and justifiable abortion.
7. What is the difference between expert testimony and other testimony. Give four positive signs of death.
8. Mention the steps necessary and on what basis may a patient be committed to an insane asylum.
9. Name three articles of diet which are tissue formers. Name four articles of diet which are work and heat producers.
10. Give dietetic treatment for typhoid fever from first day of positive diagnosis.
11. About how much water should be consumed during twenty-four hours by a person weighing 150 pounds, aside from what he obtains from his food. Name four functions of water in the system.
12. Name the chief source from which the body obtains its fat. Give dietetic treatment for apoplexy, and give your reasons for same.

PHYSIOLOGY, OPHTHALMOLOGY, AND LARYNGOLOGY.

1. Give origin, distribution, and function of the pneumogastric nerve.
2. What is the effect of alcohol on brain tissue, hepatic tissue, and stomach?
3. Write a detailed description of the function of the seventh cranial nerve.
4. Discuss briefly the physiology of the liver.
5. What would be the results of eating in excess of albuminous, oleaginous, and farinaceous foods?
6. (*a*) Discuss inflammation. (*b*) What are the functions of the skin?
7. Give function and composition of saliva, gastric juice, and bile.
8. Describe manner of using the ophthalmoscope, and name some of the diseases that can be diagnosed by its use.
9. Give diagnosis and treatment of iritis and keratitis.
10. Define hordeolum, chalazion, ptosis, astigmatism, myopia, glaucoma, and refraction.
11. Differentiate diphtheria and follicular tonsillitis.
12. Differentiate chronic laryngitis and tuberculous laryngitis, and give treatment of each.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WISCONSIN BOARD OF MEDICAL EXAMINERS.

January, 1910.

ANATOMY.

1. Occipital, 2 parictal, 2 temporal, frontal, ethmoid, sphenoid, 2 lacrymal, 2 malar, 2 nasal, 2 palate, 2 superior maxillary, 2 inferior turbinate, vomer, and inferior maxillary.
2. There are 206 *named* bones in the human body.
3. First, or olfactory, through foramina in cribriform plate of ethmoid. Second, or optic, through optic foramen. Third, or motor oculi, through sphenoidal fissure. Fourth, or trochlear, through sphenoidal fissure. Fifth, or trigeminus, through sphenoidal fissure, foramen rotundum, and foramen ovale. Sixth, or abducens, through sphenoidal fissure. Seventh, or facial, through stylomastoid foramen. Eighth, or auditory, through internal auditory meatus. Ninth, or glossopharyngeal; tenth, or pneumogastric, and eleventh, or spinal accessory, through jugular foramen. Twelfth, or hypoglossal, through anterior condyloid foramen.
4. See Cunningham's Anatomy (1909), page 607; or Gray's Anatomy (1908), page 982.
5. See Cunningham's Anatomy (1909), page 723; or Gray's Anatomy (1908), page 1113.
6. See Cunningham's Anatomy (1909), page 905; or Gray's Anatomy (1908), page 772.
7. See Cunningham's Anatomy (1909), page 797; or Gray's Anatomy (1908), pages 589, 593, 667 and 670.
8. See Cunningham's Anatomy (1909), page 754; or Gray's Anatomy (1908), page 1168.

PEDIATRICS.

1. See French's Practice (1907), page 799; or Osler's Practice (1909), pages 519 and 524.
2. See French's Practice (1907), pages 424 and 429; or Osler's Practice (1909), pages 269 and 289.

3. Enuresis. *Etiology:* Irritation of bladder, phimosis, adherent prepuce, caruncle, threadworms in rectum, fissure, overloaded rectum, stone in bladder, very acid or alkaline urine, paralysis, hip-joint disease, drinking too much fluid before bed time. *Treatment:* Remove cause, if possible; light diet, restricted fluids before bed time, light bed clothes, regular habits of urination and defecation, raising the foot of the bed, cold sponging, electricity; belladonna, bromides, ergot, cantharides and potassium nitrate have all been used for the relief of this condition.

4. *Membranous laryngitis* is practically diphtheria. See French's Practice (1907), page 184; or Osler's Practice (1909), page 200. *Synonyms:* Croup, membranous croup, angina membranacea, cynanche maligna, putrid sore throat, angina maligna, etc.

PATHOLOGY, HISTOLOGY, BACTERIOLOGY.

1. *Degeneration* is a pathological process in which abnormal substances are formed within living cells, or the entire cells are transformed into abnormal material. *Causes of fatty degeneration:* Excess of oxidizable material, heredity, diminished oxidation, high temperature, atrophy of the liver, poisons, anemia, cachexia, diabetes. *Causes of amyloid degeneration:* Suppuration, ulceration, tuberculosis, syphilis, gastroenteritis.

2. *Types:* Red or hemorrhagic, and white or anemic. *Red infarcts* are blackish red in color; have a slightly raised base; are surrounded by a hyperemic zone (if recent); are commonly found in lungs, spleen, and kidneys; the area of infarction is cone shaped, with the base at the surface of the organ, the apex pointing towards the center, and corresponding to the point of entrance and exit of the artery and vein. The blood-vessels are overfilled, due to either a backflow of blood from the veins, or to a free capillary anastomosis.

3. When the accumulation of fluid is due to circulatory disturbances it is called a *transudate;* when it is due to inflammation it is called *exudate. Transudates* do not, as a rule, coagulate, but may become slightly turbid on heating; and their specific gravity is usually below 1015. *Exudates* are rich in albumin, and so coagulate on heating; they are also rich in fibrin, and so may coagulate spontaneously; their specific gravity is usually above 1018.

4. See Rose and Carless' "Surgery" (1908), page 40; or Da Costa's "Surgery" (1908), page 81.

5. In *atrophic cirrhosis:* The liver is shrunken and indurated, rough, and of a pale or yellow color; a growth of new connective tissue is disposed in broad bands which run in various directions, and by their contraction divide the liver into numerous irregular lobes. Many acini may be affected at one time. The capsule may be thickened, or adherent to the diaphragm. Jaundice is slight, and comes on late; ascites is pronounced and may occur early.

6. In *chronic parenchymatous nephritis,* "both degenerative and proliferative changes are seen. The tubular epithelium is always more or less affected, showing signs of cloudy swelling, fatty degeneration, desquamation, and disintegration, most marked in the convoluted tubules, but also present in the loops and collecting tubules. The distribution of these changes is usually patchy, giving rise to mottling of the cortex. The lumen of the tubes may be dilated, and contain granular and fatty matters, and hyaline casts, the latter formed by coagulation of exudation in the tubules. The glomeruli may occasionally appear normal, but there is almost always some swelling and hyaline degeneration, together with some proliferation and desquamation, of the epithelium, so that they become highly cellular. Occasionally the glomerular changes may be more marked than the tubular: fatty degeneration of the glomerular and capsular epithelium may be prominent, or there may be swelling proliferation, and desquamation of the epithelium, or both these changes may be combined. The glomerular vessels may be compressed, their endothelium degenerate, and they may be obstructed by leucocytes or by hyaline thrombi, and finally obliterated. Interstitial changes, though present, are not conspicuous, and consist of edema, and scattered foci of round-celled infiltration about the glomeruli and veins. Sometimes hemorrhages are evident in some of the glomeruli and the corresponding tubules. Lardaceous infiltration frequently accompanies parenchymatous nephritis."

7. (*a*) Lipoma, myoma, neuroma, chondroma, fibroma, osteoma, odontoma, myxoma, glioma, angioma, sarcoma.

(*b*) *Malignant tumors* are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

8. The *causes of arteriosclerosis* are: Increased blood-pressure, old age, overeating, alcohol, lead poisoning, gout, syphilis, high pressure of modern life, renal disease.

In *arteriosclerosis* it is mainly the inner coat which is affected; this becomes thickened by layers of fibrous tissue owing to the proliferation of the subendothelial connective tissue cells. This thickening is not uniform. The elastic layer becomes granular, and it may be partially destroyed. Where high arterial tension exists the media is affected, and the muscle fibers become hypertrophied; sometimes degeneration occurs here. The vessels increase in length and thickness, becoming tortuous; they also feel resistant and cord-like.

9. *Diseases due to bacteria:* Typhoid, dysentery, syphilis, relapsing fever, Malta fever, influenza, bubonic plague, anthrax, cholera, diphtheria, tetanus, glanders, leprosy, tuberculosis, pneumonia, gonorrhea, cerebrospinal meningitis; and *probably:* mumps, rabies, yellow fever, whooping cough, scarlet fever, smallpox, typhus, vaccine, chickenpox, rubella, dengue, rheumatism, beri-beri, glandular fever.

Communication may be by: Air, food, drink, contact, fomites, insects.

10. (*a*) To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

(*b*) *The Widal reaction:* "Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

11. The lips, mouth, tongue, pharynx, and esophagus are all lined with stratified squamous epithelium; the esophagus, further, has mucous glands; the stomach is lined with columnar cells, has gastric glands, with shallow crypts, and acid and peptic cells; the small intestine is lined with simple columnar cells, has also goblet cells, Brunner's glands, crypts of Lieberkuhn, villi and valvulæ conniverites; the large intestine is lined with simple columnar epithelium, has goblet cells, crypts, but no villi or valvulæ conniverits; the anus is lined with stratified squamous epithelial cells.

12. See Cunningham's "Anatomy" (1909), page 1120; or Gray's "Anatomy" (1908), page 1346.

PRINCIPLES AND PRACTICE.

1. Mitral regurgitation, mitral obstruction, aortic regurgitation, aortic obstruction. See French's "Practice" (1907), page 576; or Osler's "Practice" (1909), page 796.

2. See French's "Practice" (1907), page 74; or Osler's "Practice" (1909), page 70.

3. See French's "Practice" (1907), pages 156 and 174; or Osler's "Practice" (1909), pages 172 and 189.

4. See French's "Practice" (1907), page 785; or Osler's "Practice" (1909) page 508.

5. See French's "Practice" (1907), pages 748 and 751; or Osler's "Practice" (1909), pages 473 and 477.

6. See French's "Practice" (1907), page 838; or Osler's "Practice" (1909), page 571.

7. See French's "Practice" (1907), pages 623, 626, and 628; or Osler's "Practice" (1909), pages 848 and 851.

MATERIA MEDICA AND THERAPEUTICS.

1. Formalin, hydrogen dioxide, mercury bichloride, silver nitrate, creolin, and chromic acid.

2. Arsenic. *Physiological action:* Escharotic; irritant, tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart. *Therapeutic uses:* In stomach disorders, bronchial and pulmon-

ary affections, diabetes, diarrhea, anemia, and chlorosis, chorea, malaria, and chronic skin diseases.

3. *Anthelmintics* are given by Potter as follows: For *threadworm (Oxyuris vermicularis)*—alum, ferrous sulphate, lime-water, quassia, sodium chloride, tannin, all by enema. For roundworm *(Ascaris lumbricoides)*—santonin, spigelia, chenopodium, azedarach, internally, with senna or calomel. For *tapeworms (Teniæ,* etc.)—aspidium (filix mas), kamala, cusso, granatum (pelletierine), pepo, turpentine, chloroform. For *hookworm (Uncinaria, Ankylostomum)*—thymol, aspidium.

4. (1) Hydrargyri chloridum corrosivum, gr. 1/20; (2) hydraragyri iodidum rubrum, gr. 1/20; massa hydrargyri, gr. iv; (4) hydrargyri chloridum mite, gr. ij; (5) hydrargyrum cum creta, gr. iv.

5. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

6. *Treatment of strychnine poisoning:* The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible.

7. (1) Tincture of ferric chloride, ♏viij; (2) Basham's mixture, ʒiv; (3) reduced iron, gr. j; (4) syrup of ferrous iodide, ♏xv; (5) tartarated iron, gr. iv; (6) dried sulphate of iron, gr. ij.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 164; or Hirst's "Obstetrics" (1909), page 180.

2. See Williams' "Obstetrics" (1909), page 199; or Hirst's "Obstetrics" (1909), page 188.

3. See Williams' "Obstetrics" (1909), page 235; or Hirst's "Obstetrics" (1909), page 388.

4. See Williams' "Obstetrics" (1909), page 509; or Hirst's "Obstetrics" (1909), page 238.

5. See Williams' "Obstetrics" (1909), page 672; or Hirst's "Obstetrics" (1909), page 221.

6. *Diagnosis of hydatids:* The pregnancy begins as in normal cases, but in about the third month the uterus becomes suddenly and rapidly enlarged; irregular uterine hemorrhages occur; and there is a discharge of fluid containing the vesicular growths; labor occurs, and the mass of cysts is expelled. *Treatment:* Empty the uterus as soon as possible, but beware of rupturing the uterine wall; and secure uterine contraction.

7. Puerperal eclampsia. *Etiology:* Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys. *Symptoms:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions.

8. See Williams' "Obstetrics" (1909), page 818; or Hirst's "Obstetrics" (1909), page 585.

GYNECOLOGY.

1. The *pathology of menstruation* includes: (1) Premature or precocious menstruation; (2) protracted menstruation; (3) absence of menstruation (amenorrhea); (4) profuse menstruation (menorrhagia); (5) flow in between periods (metrorrhagia); (6) painful menstruation (dysmenorrhea); (7) vicarious menstruation; (8) regular intermenstrual pain.

2. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. *Treatment* consists in removing the cause, if possible; curettage has been recommended; in the presence of developmental errors little or nothing can be done; atresia of cervix can be treated by dilatation; if the uterus is misplaced it must be replaced.

3. Metritis. *Symptoms:* Constitutional disturbances, temperature from 100° to 105° F., chills, pelvic pain, and discharge which may be profuse, offensive, purulent, or blood-stained. The vagina is hot; the uterus is tender, heavy, and bulky; later it may become fixed; the cervix is first soft, then hard and firm. *Course:* If of puerperal origin it *may be* fatal; otherwise the tendency is to recovery, after a slow and protracted course. As complications there may be: Pelvic peritonitis and cellulitis, pyosalpinx, and sterility. The disease may produce backache, leucorrhea, uterine displacements, dysmenorrhea, and sterility. *Diagnosis* can be made from above symptoms and course.

4. Curettage. *Indications:* For diagnosis, to remove pieces of retained placenta or decidua, endometritis, mucous polypi, hemorrhage, dysmenorrhea, endocervicitis. *Dangers:* Sepsis, perforation of uterus, hemorrhage, abortion, inflammation of uterus or adnexa. *Procedure:* All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu, and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going towards the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irrigated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge

NEUROLOGY, DIETETICS, MEDICAL JURISPRUDENCE.

1. (*a*) The neuron. (*b*) The *neuron* consists of a nerve cell of variable size, with nucleus, nucleolus, and one or more processes (axis-cylinder or neuraxon, and dendrites), there is no cell wall, and but little chromatin. (*c*) In *acute anterior poliomyelitis,* the anterior cornua (especially of the lumbar and cervical enlargement) are specially involved; the anterior roots atrophy.

2. (*a*) See Cunningham's "Anatomy" (1909), page 452; or Gray's "Anatomy" (1908), page 834. Pia, arachnoid, and dura. (*b*) To the disc between the first and second lumbar vertebra. (*c*) In *locomotor ataxia* the posterior columns, roots, and spinal ganglia are first involved.

3. (*a*) Seventh, facial; eighth, auditory; tenth, pneumogastric; twelfth, hypoglossal. (*b*) See below, Physiology, Questions 1 and 3. (*c*) The Gasserian ganglion is on the fifth cranial nerve, and is situated in Meckel's hollow, near the apex of the petrous portion of the temporal bone.

4. (*a*) See Cunningham's "Anatomy" (1909), page 648; or Gray's "Anatomy" (1908), page 1030. (*b*) Internal and external popliteal. (*c*) Anywhere between the sacral plexus and the lower third of the thigh.

5. (*a*) The pneumogastric and the sympathetic. (*b*) The former is the inhibitory nerve and slows the heart; the latter augments or accelerates the beats.

6. When abortion is undertaken by properly qualified physicians after due consultation with other physicians, and for the purpose of saving the life or health of the mother, it is *justifiable;* under all other circumstances it is *criminal.* The former is a perfectly lawful medical procedure; the latter is illegal.

7. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically,* this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practice is accepted as an expert witness.

In *ordinary* testimony, the witness testifies to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

Four positive signs of death: (1) The permanent cessation of circulation; (2) the permanent cessation of respiration; (3) rigor mortis; (4) putrefaction.

8. In Wisconsin: The words "insane persons" include idiots, persons *non compos mentis*, lunatics, and distracted persons. Any three citizens may apply to the county court for a judicial enquiry and an order committing a person to a State hospital. Two physicians are appointed as examiners in lunacy. The form of their report is prescribed. Insane persons may also be admitted as voluntary patients upon two physicians' certificates.—(From Witthaus and Becker's *Medical Jurisprudence*, etc.)

9. *Tissue formers:* Lean meat, eggs, wheat. *Work and heat producers:* Bread, butter, sugar, potatoes.

10. See French's "Practice" (1907), page 111; or Osler's "Practice" (1909), page 99.

11. About 65 to 70 ounces of water are required, besides what is obtained from the food. *Four functions of water:* (1) It is the chief ingredient of the fluids of the body; (2) it serves as a distributor of body heat; (3) it regulates the body temperature (by means of absorption and evaporation); and (4) it enters into the chemical composition of the tissues.

12. The fat of the body is obtained from fatty foods, from carbohydrates, and from proteids.

In *apoplexy* the diet must be light, nutritious, and unstimulating, and consist chiefly of milk and farinaceous foods. Animal food is best avoided, or limited to fish; alcohol, tea, and coffee are also best avoided. A vegetarian and milk diet is best, but individual peculiarities have to be studied. Rectal feeding may be necessary. The reason for the reduced diet is to reduce arterial tension, and so prevent a recurrence of the hemorrhage. Intravascular pressure must also be kept low, hence too little fluid must not be given, and the kidneys should be kept active with diuretics.

PHYSIOLOGY, OPHTHALMOLOGY, AND LARYNGOLOGY.

1. Pneumogastric nerve. *Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric. *Function:* It supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc.

2. *Alcohol* excites, then depresses the brain; in small doses it stimulates the stomach and may help digestion; later it congests the stomach and liver, over-stimulates the gastric glands and hepatic cells, causes gastric catarrh, produces pathological conditions, and impairs digestion.

3. The facial nerve is the motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscles of the external ear, the stylohyoid, and the posterior belly of the digastric. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands. Hence section of the nerve would cause abolition of these various functions; notably, facial paralysis would ensue. When it is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums.

4. A lobule of the liver is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the hepatic cells are packed.

The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

5. *Excess of albuminous food* may cause: Congestion and enlargement of the liver, plethora, imperfect oxidation and elimination, delayed metabolism, fever, malaise, diarrhea, albuminuria, calculus, lithemia, torpor, and biliousness. *Excess of oleaginous food* may cause: Delayed nitrogenous assimilation, production of excessive fat. *Excess of farinaceous food* may cause: In addition to same as excess of oleaginous food, acidity and flatulence, corpulence, enfeebled heart action, dyspepsia, and glycosuria

6. (*a*) *Inflammation* is the series of changes which occur in a part as the result of injury, provided the injury is not so severe as to destroy the tissues; it is the "reaction of the tissues to injury." (*b*) *The functions of the skin* are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

7. Saliva. *Functions:* (1) To moisten the mouth; (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste; (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar. *Composition:* Water, mucin, ptyalin, potassium sulphocyanide, proteid, sodium chloride, and other salts.

Gastric juice. *Functions:* To convert proteids into proteoses and peptones, to curdle milk. *Composition:* Water, pepsin, hydrochloric acid, chlorides, and phosphates.

Bile. *Functions:* (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metaholism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action. *Composition:* Water, sodium glycocholate, sodium taurocholate, lecithin, cholesterin, pigment, and inorganic salts.

8. *Use of the ophthalmoscope:* "The patient is placed in front of the source of illumination, and to the side of the eye to be examined, the light behind him so that it shines on his temple, just touching the tips of the outer lashes. He is then told to look straight ahead to an object on a level with his eyes across the room. To examine the patient's right eye the surgeon sits or stands, and holds his ophthalmoscope in his right hand before his own right eye. To examine the patient's left eye he places himself to the left of the patient and holds the ophthalmoscope in his left hand before his own left eye. The ophthalmoscope is brought close to the eye under examination, the mirror of the ophthalmoscope having been inclined and the instrument held in such position that the light from the source of illumination will be reflected directly into the patient's pupil; then, if the media are clear, a red glare called the fundus reflex is seen through the hole in the mirror. If the examiner wears glasses, he need not remove them; in fact, if he is astigmatic, he had better accustom himself to working with his correcting lenses on."—(From Gould and Pyle's *Compend.*)

Diseases which can be diagnosed by its use: Brain tumors, abscess of brain, anemia of brain, cerebral aneurysm, tabes dorsalis, multiple sclerosis, exophthalmic goiter, nephritis, diabetes, hypertrophy of the left ventricles of the heart, fatty degeneration of the heart, syphilis, alcoholic or tobacco poisoning.

9. Iritis. *Symptoms:* Pain, photophobia, small pupil, ciliary congestion, discoloration of iris, exudate in anterior chamber. *Treatment:* Causal, abstraction of blood from temples, atropine, diaphoresis, shielding the eye from light. Keratitis. *Symptoms:* Pain, photophobia, ciliary injection, blepharospasm, impairment of vision, cornea *moy* be perforated. *Treatment:* Causal, atropine, tonics, and symptomatic.

10. *Hordeolum* is an abscess or inflammation in the tissues about the follicle of an eyelash. *Chalazion* is a tumor in the eyelids due to obstruction of the duct in a Meibomian gland. *Ptosis* is a drooping of the upper eyelid, generally due to paralysis. *Astigmatism* is a condition in which, owing to a greater curvature of the eye in one

meridian than in others, the refractive power of the eye varies. *Myopia* is a condition in which the anteroposterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina. *Glaucoma* is a disease of the eye due to increased intraocular tension, and resulting in excavation and atrophy of the optic disc, and finally blindness. *Refraction* is the deviation produced in the course of a ray of light in its passage from one medium to another. Also, the act or process of refracting.

11. In *diphtheria* the onset is more gradual; the temperature rises to about 101° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

12. See French's "Practice" (1907), pages 645 and 360; or Osler's "Practice" (1909), pages 597 and 600.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	June —
Arizona*	Ancil Martin, Phoenix	Phoenix	April 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 5
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 12
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	April 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	April 4
Georgia	E. R. Anthony, Griffin	Atlanta	April —
Idaho*	W. F. Howard, Pocatello		April 5
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	July 12
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	F. P. Hatfield, Olathe	Topeka	June 14
Kentucky	J. N. McCormack, Bowling Green	Louisville	July —
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 17
Maine	F. W. Searle, Portland	Portland	July —
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 7
Massachusetts*	E. B. Harvey, State House, Boston	Boston	July 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 14
Minnesota	W. S. Fullerton, St. Paul	St. Paul	May 10
Mississippi	S. H. McLean, Jackson	Jackson	May 10
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	June 13
Montana*	Wm. C. Riddell, Helena	Helena	April 5
Nebraska	C. A. Carr, Lincoln	Lincoln	Aug. 3
Nevada	S. L. Lee, Carson City	Carson City	May 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	July 6
New Jersey	H. G. Norton, Trenton	Trenton	June 21
New Mexico	J. A. Massie, Santa Fe	Santa Fe	April 11
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo	May 24
N. Carolina	B. K. Hays, Oxford	Wrightsville	June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 4
Ohio	Geo. H. Matson, Columbus	Columbus	June 14
Oklahoma*	F. P. Davis, Enid	Guthrie	April 12
Oregon	B. E. Miller, Portland	Portland	July 5
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg	June —
Rhode Island*	G. T. Swarts, Providence	Providence	April 7
S Carolina	H. H. Wyman, Aiken	Columbia	June —
S. Dakota	H. E. McNutt, Aberdeen	Watertown	July 13
Tennessee	C. A. Abernathy, Pulaski	Memphis / Nashville / Knoxville	May —
Texas	M. E. Daniel, Honey Grove	Austin	June 28
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	April 4
Vermont	W. Scott Nay, Underhill	Burlington	July 12
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	T. C. McFadden, Seattle	Spokane	July 5
W. Virginia	H. A. Barbee, Point Pleasant	Wheeling	April 12
Wisconsin	J. M. Beffel, Milwaukee	Madison	July 12
Wyoming	S. B. Miller, Laramie	Laramie	June 22

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Indiana.—Reciprocity has been established, under certain conditions, between this State and New York.

Virginia.—Reciprocity now exists between Virginia and North Carolina. It is proposed to divide the examination in this State, so that candidates may take half of the subjects at a time. The fee for reciprocity for those coming into, or going out of, the State is $25.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of March 5, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	985	177
Diphtheria	390	43
Measles	1,703	31
Scarlet Fever	703	43
Smallpox	—	—
Varicella	212	—
Typhoid Fever	30	5
Whooping Cough	36	2
Cerebrospinal Meningitis	5	7
Malarial Fever	—	—
Totals	4,064	308

For Night Sweats.—According to Griffin, camphoric acid in 15-grain doses and a sponge in tepid water and vinegar is usually sufficient.—*Memphis Medical Monthly.*

Vaseline Oil in the Abdomen.—Wilkie says that he feels justified in advocating the introduction of vaseline oil into the peritoneal cavity in the following conditions: 1. In operations for the relief of old-standing adhesions. 2. In operations for localized or diffuse peritonitis, where handling of the viscera is unavoidable. 3. In operations for generalized peritonitis to favor subsequent drainage and intestinal peristalsis.—*Surgery, Gynecology, and Obstetrics.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 4, 1910:

		CASES.	DEATHS.
CHOLERA.			
India, Bombay	Jan. 19–25	..	3
Calcutta	Jan. 9–15	..	15
Rangoon	Jan. 9–15	..	4
Java, Batavia	Jan. 9–15	1	1
Philippine Islands, Manila	Jan. 2–15	28	20
Provinces—			
Bataan	Jan. 2–15	12	10
Cebu	Jan. 2–15	9	14
Leyte	Jan. 2–15	22	21

THE METHOD OF RESPIRATION BY INTRATRACHEAL INSUFFLATION, ITS SCIENTIFIC PRINCIPLE AND ITS PRACTICAL AVAILABILITY IN MEDICINE AND SURGERY.*

By S. J. MELTZER, M.D., LL.D.,

NEW YORK.

[From the Department of Physiology and Pharmacology of the Rockefeller Institute for Medical Research.]

Respiration means in general the supply of oxygen to and removal of carbon dioxide from the animal body. In lower organisms the exchange of gases takes place on the surface, perhaps exclusively by the physical process of diffusion. The surrounding medium contains more oxygen and less carbon dioxide than the animal tissues; and each gas diffuses through the permeable surface membrane of the animal in the direction of diminished tension, that is, oxygen enters into the body and carbon dioxide leaves it. In higher animals, especially in the higher vertebrates, we have to distinguish between an *internal* and *external* respiration. The exchange of gases in the internal respiration takes place between the tissues and the blood capillaries. The mechanism is here nearly the same as in the respiration of the lower organisms. The arterial blood, which contains more oxygen and less carbon dioxide than the tissues, while passing through the capillaries gives up oxygen to and takes up carbon dioxide from the tissues also by diffusion. The accumulation of the carbon dioxide and the exhaustion of oxygen within the capillary blood is prevented by the *continuous flow* of the blood. In the lower animals this result is obtained by the movements of the animals within the medium and by currents of the medium which are in some cases sustained by ciliary movements on the surface of the animal. The external respiration takes place within the lungs. Here we have again to distinguish two parts of the function: one part which attends to the exchange of the gases between the alveolar air and the lung capillaries and another part which attends to the maintenance of the proper composition of the gases in the alveolar air. The first part of the mechanism does not differ essentially from the corresponding part in the internal respiration. In the alveolar air the percentage of oxygen is greater and that of the carbon dioxide is smaller than in the lung capillaries; oxygen therefore is given to and carbon dioxide taken from the pulmonary circulation. The other part of the function of external respiration presents here a new problem and requires a complicated mechanism for its proper solution. The numerous alveoli with their extensive respiratory surface may be considered as one huge cavity containing at the end of a normal expiration about 3000 c.c. of air, that is 1500 c.c. *reserve* and 1500 c.c. *residual air.* The tension of the carbon dioxide in this air is relatively only slightly less than that of the lung capillaries and the difference between the tensions of oxygen in the capillaries and the alveoli is not very great either. Without a frequent renewal of the air in the alveoli the differences would be completely swept away in a few minutes; no exchange of gases could then take place and the animal would die of asphyxia. If the alveoli would open up directly into the surrounding air, for instance, like the system of *tracheæ* in insects, or myriapodes, a small contrivance would suffice to accomplish the proper exchange of the gases in the alveolar air by means of simple diffusion. However, as it is, the alveoli are connected with the air surrounding the animal body by means of long, narrow, and tortuous canals; the small and large bronchi, the trachea, and the larynx and the pharynx, mouth, and nose. The efficient exchange of the gases can be accomplished here only by a proper *system of ventilation.* We know the system which nature employs; it differs in one essential from the method employed for the purpose of renewal of the medium carrying the gases in the respiration of the lower organisms or in the internal respiration of the higher animals. While here the renewal of the medium is attended by a continuous movement going only in one direction, the renewal of the alveolar air in the lungs is accomplished by alternating movements going in the opposite direction. The external respiration, or simply the respiration, as it is generally designated when speaking of higher animals, is accomplished here, as is well known, by two separate actions: the inspiration and the expiration. During the inspiration the thoracic cavity becomes distended by the force of muscular contraction and a quantity of air is aspired into the lungs; during the immediately following expiration a similar quantity of air is driven out again by the elastic force of the tissues which become overdistended during the inspiration. The quantity of air temporarily inspired, known as the *tidal air,* is comparatively small, only about 500 c.c., and one-third of this air remains in the dead space that is in the bronchi, the trachea, etc., and does not come in direct contact with the air in the alveoli. The exchange of the gases between the tidal air and the air in the alveoli takes place by diffusion which, however, is probably greatly accelerated by some sort of shock, brought about by the respiratory movements, which assists in mixing the two kinds of air more rapidly and intimately. The exchange takes place with too great rapidity to explain it by the action of diffusion alone; carbon dioxide is present even in the upper part of the air column already at the beginning of each expiration,

*Read at the New York Academy of Medicine, February 17, 1910.

although this part is separated from the alveolar air by a long *dead space.*

The efficiency of the system of ventilation in the normal animal depends upon the normal activity of the inspiratory muscles and the intact condition of the thoracic cavity. When the latter is not air-tight or when the activity of the inspiratory muscles are greatly impaired by disease or drugs, the ventilation fails and the animal dies from asphyxia. To meet such emergencies, an efficient method of artificial respiration is in vogue for a long time, at least in animal experimentation. It has been practised incidentally by Vesalius in the sixteenth century and has been systematically used by Robert Hook in the following century; it is now, as is well known, one of the regular methods in use in physiological laboratories. It is in substance an exact imitation of the normal ventilation, each respiration consisting of a cycle of two opposite movements, except that the inspiration is accomplished by blowing air by some external force instead of aspiring it; the expiration is accomplished exactly in the same manner and by the same forces as in a normal expiration of a normal animal.

In the course of experiments which Dr. Auer and I have carried out last year we discovered that the ventilation of the alveolar air can be satisfactorily accomplished in a similar manner as the one which is acomplished in the internal inspiration, that is by *a continuous movement in one direction.* When through an opening in the trachea a tube, of a diameter which is distinctly smaller than the lumen of the trachea, is introduced so as to have the lower end reach the bifurcation, or resting loosely even within the upper end of one bronchus, a stream of plain air, sent continuously through this tube, will keep up the life of even a completely curarized animal. The pressure by which the air is driven need not be more than 10 or 12 millimeters of mercury. The chief requirement for the success is that the lower end of the tube should reach the bifurcation. When the tube does not reach deeper than the usual tracheal cannula, the curarized animal dies in a short time. The deeper the tube reaches, the longer does the animal live; but the complete success can be attained only when the tube reaches the bifurcation or reaches a bronchus. Another requirement is that the tube should fill out about two-thirds of the lumen of the trachea; when it is wider, there is not enough space between the tube and the tracheal wall for the return of the air carrying the carbon dioxide, and when it is too narrow, there seems to be not enough supply of the air conveying the oxygen. We had dogs which under this system of ventilation were for four hours and longer under the influence of curare and recovered either by getting out spontaneously from the influence of curare or by the use of physostigmin which is a pretty good antagonist to curare. Similar successes we had when the tube was introduced through the mouth and larynx into the trachea; but on account of the greater narrowness of the larynx it is more difficult to adjust the diameter of the tube to that of the lumen of the larynx.

In non-curarized animals the continuous intratracheal insufflation of air under a moderate pressure reduces the voluntary respirations of the animal to 8 or 6 times per minute. With an increase of the pressure to 20 or 25 millimeters mercury a complete apnea may be obtained. In this case the heart becomes very slow, from which check however it is easily freed by a small dose of atropin. Whether the animal is in a state of apnea from pressure or is freed from voluntary respirations by curare or by any of the methods which eliminate the respiratory center, when the thorax is widely opened, the lungs are found more or less distended, of pink color and completely quiet, while the heart is beating efficiently and regularly.

The fact that the success of the method of the intratracheal insufflation is the more assured the deeper the tube is in the trachea, indicates that the favorable factor in this method of ventilation is to be found in the circumstance that it cuts out the largest part of the dead space. The oxygen carrying pure air reaches the upper end of the bronchi continuously and under a pressure and with a velocity which are greater than normal and removes from there any accumulated carbon dioxide also continuously and with a pressure and a velocity again greater than normal. The exchange of the gases within the bronchi and the alveoli occurs probably essentially by diffusion. It is, however, probable to me that the stream of air which comes out from the tube continuously about the level of the bifurcation with unusual pressure and velocity reaches out farther than this level* and at the same time sets up currents and disturbances in the mechanical equilibrium of the gases within the bronchi and the alveoli which are capable of influencing favorably the diffusion processes. Furthermore the continuous distention of the lungs produced by the insufflation increases the alveolar cavity as well as the respiratory surface, two factors which are capable of influencing the respiratory exchange of gases in a favorable direction.

In the method of pulmonary ventilation as described above the distinguishing points are that the insufflation is continuous, that it is done under higher pressure, that the respiration is sustained simply by air, that the current does not pass out through another normal or artificial opening, but returns through the same normal canal through which it entered, the canal being divided into two paths by an artificial partition; and finally that the pressure within the trachea remains throughout the insufflation higher than in the pharynx and that there is therefore a continuous stream of air moving in the direction from the trachea towards the pharynx. At a later point we shall discuss particularly the advantage of the last mentioned point.

Regarding the continuous character of insufflation we wish to recall to mind that this is the normal method of ventilation in the internal respiration and that in many aquatic animals with bronchial respiration the water enters mostly continuously through one opening, passes over the gills, and leaves through another opening. In mammals the possibility of keeping up life by a continuous stream of air was demonstrated by Robert Hook in the seventeenth century. After piercing holes in the lungs of a dog for the purpose of escape of the air he kept up the life of a dog with an open thorax by blowing in air continuously through the trachea by means of the action of double bellows. In birds the cavities of the long bones are connected with the air sacs. Nagel† reported about ten years ago that in curarized pigeons he kept up the life of the animals as long as two hours by blowing continuously through the cavity of the humerus; the es-

*We shall see later that dust within the tube is being carried to the finest bronchi.

†W. Nagel, *Centralblatt für Physiologie,* Vol. XIV, 1900, p. 553.

cape of the air took place through the trachea. In these two instances the insufflation of air was continuous, but it escaped through openings opposite to those through which the insufflation was instituted and both methods had the advantage that the alveolar air was ventilated directly without the mediation of any part of the dead space.

Under the title "Artificial Respiration by Means of Ventilation of the Trachea," F. Volhard* reported about two years ago interesting results which have some bearing on our subject. By permitting oxygen to pass into the trachea of dogs through a tube introduced through the larynx or by passing a stream of oxygen in front of a cannula tied in the trachea of rabbits, Volhard was able to maintain the life of curarized animals for one or two hours; they never lived longer than two hours and they could not be restored by means of physostigmin after they had been for one hour under the influence of curare. Volhard states expressly that the stream of oxygen in his experiments was never strong enough to cause a distention of the lungs. The experiment never succeeded with air.

There are definite differences between our observations and that of Volhard. Volhard could not keep up the life of his animals when using air; our insufflations are made with air. Even with pure oxygen Volhard could not keep up the life of the curarized animals longer than two hours; we kept them alive for more than four hours, in fact we can keep them alive as long as we wish. In Volhard's experiments there was not enough pressure to distend the lungs; we lay stress upon the use of increased pressure and emphasize especially the importance of the increased pressure in the returning current. We insist futher upon the tube reaching the bifurcation believing that the cutting down of the "dead space" being an important factor in the success of our method of insufflation, while Volhard does not indicate how deep in the trachea the tube was inserted in his experiments.

While we thus can justly claim that our method differs essentially from that of Volhard and is by far more efficient, we readily appreciate the importance of the observations made by Volhard. They demonstrate the significant fact that a luxurious supply of oxygen is capable of considerably neutralizing the evil effects of the accumulation of carbon dioxide, a surprising fact which seems to be diametrically opposite to the opinion of authoritative physiological workers in this line.

A part of Volhard's experiments was published a few years ago by Hirsch, a pupil of Volhard, in a thesis. It was widely abstracted and was the cause that various experimenters in this country employed it. Sollmann discussed that subject before a medical society in Cleveland, but he never published this paper. Robinson† refers to the procedure of the oxygen insufflation as the Volhard-Sollmann method.

Before leaving this part of my paper I should mention that in a few experiments I tried to attain ventilation by means of intratracheal *suction* instead of insufflation. In no case could the life of the curarized animal be sustained for any length of time and in one case the animal died soon of pulmonary edema.

*F. Volhard, *Münch. med. Wochenschrift*, 1908, p. 209.

†In experimenting with this method Robinson was apparently on the way of developing the intratracheal insufflation method, but was distracted from this end by becoming interested in improvements which he made in the Brauer method. *Jour. Am. Med. Assn.*, Vol. LI, p. 803.

In the experiments described in the foregoing part the purpose predominated to establish the theoretical principle that the object of the external respiration can be efficiently attained by means of an intratracheal ventilation without the aid of muscular action and without the rhythmicity of alternating movements. Our attention, however, was soon turned toward the practical availability of this method of artificial ventilation. The objections to the practical application of the method as it stood then lie in the first place in the necessity of having an exact proportion between the diameter of the tube and the lumen of the trachea. Even when the tube had been introduced through an incision in the trachea, it was not always easy to strike the right proportion; and the problem of adjustment became still more difficult when the attempt was made to introduce the tube through the larynx. Soon, however, we made an observation which gave us the key for the removal of this obstacle. In experiments in which the tube did not seem to be well adjusted and the color of the lungs as well as the action of the heart indicated the imminent danger of asphyxia it was found that the interruption of the air stream for a second or two would avert the danger. It is an instructive phenomenon to see a lung which a second before was definitely cyanotic becoming pink immediately after a very brief collapse. Apparently the momentary collapse and distention assist greatly in the exchange of the gases within the bronchi and alveoli. It was then arranged to have the air stream interrupted once or twice a minute for a second or two, and it was found that under these circumstances the life of curarized animals can be carried on safely by insufflation through tubes of even fairly small diameters. I have since carried on often prolonged ventilations in dogs of 5 or 6 kilos' weight through tubes with a diameter smaller than 2 millimeters. Furthermore, it is not necessary to have the lungs completely collapsed; a moderate reduction in the intratracheal pressure is sufficient to maintain an efficient ventilation. In fact, when the interruption is discontinued for only a second or two, the reduction in the distention of the lung is, as a rule, indeed only moderate; there is not enough time for a real collapse. This short slight change in the volume apparently suffices to supplement efficiently the exchange of gases carried on incompletely through the small tube.

In cases of open pneumothorax in which the respiratory mechanism is not paralyzed, the spontaneous respirations of the animal itself offer the required aid to the continuous insufflation through narrow tubes. However, even here it is safer to arrange for an occasional short interruption of the continuous insufflation, especially in operations in which the thorax has to be wide open and the posterior and inferior parts of the lungs have to be dislocated, in which condition the spontaneous respirations of the animal are of no avail at all. The occasional interruption of the air stream insures the continuance and efficiency of the pulmonary ventilations under all circumstances.

With this new information in mind another important practical step forward was made, namely, that the insufflation could be carried on henceforth through tubes which were introduced into the trachea through the larynx. While the size of the tubes had to vary to a degree with the size of the dogs, care was taken chiefly that the tubes should not be too large, preferring the error in the direc-

tion of having them rather too small than too large. The occasional interruptions of the insufflation correct more easily the errors which come from too small tubes than those which come from too large tubes.

The large number of experiments carried on in the last months upon the subject of intratracheal insufflation were made with a view largely to study some of the practical problems connected with the method of intratracheal insufflation.

The first question which naturally arose was: Is this method capable of doing any harm to the respiratory organs? Will not the prolonged presence of the tube within the entire length of the trachea and the continuous insufflation of air into the bronchi frequently cause pneumonia, bronchitis, or do some other damages to some part of the respiratory organs? As an answer to this important question I am able to state that we have now quite a sufficient number of observations at our disposal from which some definite conclusions may be drawn. Besides our own numerous experiments Dr. Carrel employed for the last few months the method of intratracheal insufflation in a large number of intrathoracic operations and so did also Dr. Elsberg who carried on his experimental surgical work in our department at the Rockefeller Institute. I do not know the exact total number of all these experiments and operations. Surely about a hundred dogs have been operated upon by the method of intratrachael insufflations. The operations lasted sometimes two hours and longer. Some of the animals survived and are still alive; others came to autopsy sooner or later after the operations. *In not a single instance did an animal die from the effects of the insufflation or did the respiratory organs show any after-effects of the method.* Neither pneumonia nor bronchitis ever developed in these animals; nor was there any pulmonary emphysema when the lungs were examined days or weeks after the operation. This experience seems to demonstrate quite satisfactorily that the respiratory organs of the animal are not exposed to any special danger by the employment of the method of intratracheal insufflation.

Another problem which had to be studied was the following: Since the tube in the larynx may prevent the complete closure of the epiglottis, it could be assured that there might be danger from aspiration into the lungs of foreign, infectious material from the pharynx, especially if vomiting should occur in the course of an operation. I have investigated this point by special experiments. I shall state in the first place that none of the dogs in which the method of intratracheal insufflation was employed vomited either during or after the operation. In order to study the effect of vomiting I had to employ subcutaneous injections of apomorphin. I shall give the results very briefly. When the stomach was empty before the operation, apomorphin failed to bring on vomiting even after the animal awoke from the anesthesia. When the stomach was full by previous feeding or filled up by a stomach tube with a strongly acid fluid before the introduction of the tube into the trachea, the animal never vomited even after large doses of apomorphin as long as it was under the influence of anesthesia. Under these circumstances, however, the animals vomited sometimes 10 or 15 minutes after the anesthetic was discontinued. In order to have a severe test, pharynx and mouth of the animals were not cleaned and after some time the trachea was exposed, the tube withdrawn, and the trachea clamped beneath the larynx. *On opening the trachea it was found to be perfectly free from the vomited material and the mucous membrane to have an alkaline reaction,* although the stomach contents were made strongly acid. In other experiments a suspension of charcoal was introduced into the mouth and the pharynx and later on the trachea was examined in the manner described before; *not a particle of the charcoal could be detected in any part of the trachea or even larynx.*

Immunity of the trachea against the invasion of substances from the pharynx is here not a matter of accident; it has its reasons, as I believe, in the fact that in the method of intratracheal insufflation there is present within the trachea a strong air current which is capable of driving everything from here to the larynx and certainly can prevent the invasion of any foreign body from the pharynx into the trachea. It is not improbable that the exceptional freedom from postoperative intrapulmonary infections in the numerous animals which were subjected to the method of intratracheal insufflation finds its explanation in the very same condition, namely in the protective action of the current directed outwardly while the insufflation continues. It seems to me that *this factor of the outward direction of the current is an important and practical feature of the method of intratracheal insufflation.*

Another important and practical feature which we have observed in this method is its relation to anesthesia. A noteworthy fact is *the remarkable ease with which the animals become anesthetized.* They may be completely out of the anesthesia; a minute or two after the ether is turned on again they sink into the deepest state of anesthesia with no lid reflex and the body perfectly quiet and limp. They may be kept in this state uninterruptedly for two hours and longer. Again the animals get out of the deepest state of anesthesia in a comparatively short time as soon as the ether is discontinued. This awakening can be hastened by sending through the tube a stream of pure air. Furthermore, it is an instructive fact that except for one death caused by extraneous circumstances *not a single animal was lost by ether when employed by the intratracheal method.* This observation may not be of such importance since in matters of anesthesia an experience gained in 100 cases cannot be considered as very extensive. However, I am able to report the results of two series of experiments which demonstrate clearly the great advantage which this method offers to ether anesthesia. In the first place I have tried in a number of cases in which the insufflation was employed to cause the death of the animal by the anesthesia, pushing the ether to the utmost and increasing also the pressure of the air stream in order to drive more ether into the lungs. *I did not succeed in accomplishing it even in a single instance.* In fact, it seemed that the use of larger quantities of ether did not bring the animal into a deeper state of anesthesia than it already is when only a moderate amount is used.*

Furthermore I have carried out a series of experiments in which dogs were killed by ether in the usual mode of administration and then attempted

*Even for the use of chloroform the method seems to offer a good deal of safety; but I have succeeded in killing one animal by this method when a great deal of the chloroform was used. Altogether I did not make many experiments with chloroform.

to revive them by the intratracheal method of artificial respiration. Usually some time has to pass before everything is properly adjusted and the resuscitation begins as a rule only after the heart has stood still for a few minutes. In addition to the respiration in all cases also the thorax was massaged. The results of these experiments are very interesting, but I should not discuss here their particulars. I had a few animals which were *completely resuscitated after there were no heart beats for* 15 *minutes.* In one case resuscitation took place 21 minutes after heart death. In this case and in some others a small dose of adrenalin and 50 or 60 c.c. of Ringer solution were administered intravenously. I may say in general that my impression is that *dogs, especially younger ones, can be invariably resuscitated from ether poisoning by the intratracheal method of respiration,* supported by massage of the thorax if the resuscitation is not started too long after the heart stopped. At any rate, if the tube is already in the trachea while the heart just stopped beating, it is quite sure that the immediate institution of the insufflation will restore the life of the animal in a short time even without the aid of any cardiac massage. On the basis of my observations and experiments it seems to me that *the giving of ether by the method of intratracheal insufflation is the safest and most effective way of administration of this anesthetic.* The bringing of the ether by increased pressure to the very proximity of the respiratory surface hastens its effect and the continuous returning current of air prevents its too great accumulation in the bronchi and alveoli. In our laboratory we are using at present this method of anesthesia for any operative work on the dog with complete satisfaction, paying no further attention to the etherization except of pouring now and then ether into the bottle. At the same time the animals are under the present method in deeper anesthesia than they were ever kept, while less ether is used up.

In all our experiments in the laboratory the continuous air stream was provided by an air pump connected with our respiratory apparatus. However, we soon found out that a continuous stream can be satisfactorily maintained simply by foot bellows such as are used for glass blowing. The pressure can be kept fairly uniform; besides, we know now that an occasional variation of the pressure is rather an advantage to the ventilation of the lungs. The intratracheal insufflations in the intrathoracic work of Dr. Carrel in his operating room and in the operation of Dr. Elsberg in our laboratory are carried on by means of such bellows.

I shall now describe connectedly and briefly the entire procedure of the intratracheal insufflation in the simple fashion as we are using it now. After the dog is well anesthetized, a long catheter or a piece of stomach tube is introduced through the larynx and pushed down the trachea until it meets an obstacle. The lower end is then usually deep in the right bronchus. It is then withdrawn about an inch and a half, which brings the lower end of the tube to about the level of the bifurcation. By experience I have learned that it is advantageous to provide the lower end of the tube or the catheter only with one opening which should be located at the end point. The diameter of the tube may vary between 3 to 8 millimeters and depends upon the size of the dog; it should be definitely smaller than the lumen of the larynx; it should rather appear too small than too large. The outer end of the tube is carried through the hole of a gag around which the jaws of the animal are tied. By means of a thread which is tied to the gag the tube is held in a fixed position. The outer end of the tube is now connected with a T-tube, one branch of which goes to a manometer, while the other end is connected with a bottle containing ether, which in turn is connected by means of heavy rubber tubing with the bellows. The ether is in a Wulff's bottle, which by means of two Y-tubes, rubber tubing, and clamps, is arranged so as to permit the current of air to pass either through the bottle or directly between the bellows and the animal. The tube between the bottle and the bellows should be provided with a T-tube or plain opening which the assistant who attends to the bellows and the ether keeps closed with his finger and opens it only for a second a few times in a minute. As stated above, this is a precaution which insures an efficient ventilation of the lung. This opening should be kept closed when vomiting is threatening in order to keep up the high intratracheal pressure.

For the purpose of filtering the air driven into the trachea it is advisable to interpolate between the bellows and the ether bottle a tube containing cotton. As a matter of fact in our experiments we have employed such a tube only in exceptional cases and nevertheless we never have seen any ill results from such an omission. However, in prolonged operations I found that there was sometimes dust at the bottom of the ether bottle; it is possible that in these cases the ether bottle served as a filter. Furthermore in experiments in which some powdered charcoal was introduced in some part of the tubing connecting the ether bottle with the intratracheal tube, fine particles of charcoal were found to reach the finest bronchi. We have, therefore, some reason to suppose that dust could be carried through the tube and deposited into the depths of the lungs. Such an event is to be kept in mind, especially when using bellows placed on the floor where dust can be readily sucked in.

It is perhaps not superfluous to point out here the obvious difference between the currents existing in the intratracheal tube and in the space between the tube and the surrounding trachea. In the tube the direction of the current is towards the lungs and the air there can and ought to be guarded against any contamination from outside. In the space between the tube and the tracheal wall the direction of the current is away from the lung and movable particles there are carried outside of the body. The last fact was well illustrated in the last cited experiments; the bulk of the powdered charcoal which was blown down the tube, a small fraction of which reached the fine bronchi, was returning immediately in a stream through mouth and nose as through a chimney.

As a further precaution some may wish to append a device for warming the air before entering the tube. From my own experience I am inclined to think that such a device is an unnecessary burdensome complication, from which the arrangement for intratracheal insufflation should be kept free.*

The arrangement for intratracheal insufflation, as I have just described, is surely simple, inexpensive, portable, and readily prepared at a moment's notice.

I have previously stated the distinguishing theo-

*I should state here that in operations upon the thoracic cavity, before closing the same, the trachea should be compressed for a few seconds; it will cause a distention of the lungs and fill up the cavity.

retical points which characterize our method of pulmonary ventilation. I wish to compare here briefly from a practical point of view the method of intratracheal insufflation with the methods now variously employed in experimental and practical intrathoracic surgery for the purpose of maintaining the differential pressure.* Obviously our method has in common with the so-called overpressure method the fact of the increase of the intrapulmonary tension. Both methods, however, differ greatly in various points. In the first place the intrapulmonary pressure in Brauer's method is of a *static* character, that is, that after the initial increase of the pressure, there are during the remainder of the course, as was pointed out by Seidel, no air currents, no movements within the lungs, the overpressure is stationary; whereas in the intratracheal insufflation the air which is also under higher pressure is at the same time in continuous motion. Furthermore, in the Brauer method the ventilation is carried out by the respiration of the animal itself, while in our method the ventilation is efficiently carried on without the aid of the animal. When the animal is curarized or when the spontaneous respiration fails for some other reason, under the Brauer method the animal dies within a few minutes; while in our method the life of the animal remains safe under all circumstances. Other factors of the method of intratracheal insufflation are the safety of the etherization and the presence of a centrifugal air current within the trachea which is capable of keeping away from the lungs the invasion of injurious elements. It may finally be stated in general that the overpressure method is made only to meet the exigencies of the pneumothorax while the intratracheal insuéation is capable of meeting exigencies of all kinds which may befall the function of respiration, in fact it acts as an efficient artificial respiration. It differs, however from the usual rhythmical artificial respiration, in that the supply of oxygen as well as the removal of carbon dioxide are carried on simultaneously and continuously, whereas in the customary artificial respiration the cycle is distributed between the inhalation of oxygen, exhalation of carbon dioxide, and an inactive intermission. Furthermore, in my opinion, the intratracheal insufflation method has the advantage over the usual artificial respiration in that it offers a greater safety to the etherization and it is guarding the lungs against undesirable invasion.

The differences between our method and that of Volhard I have already discussed above. Besides, Volhard's method could not meet the exigencies of pneumothorax.

The method of intratracheal insufflation has, furthermore in common with the methods employed by Franz Kuhn,† the fact of the peroral intubation. However, Kuhn's peroral tube, which is inserted nearly tightly into the larynx, avoids studiously deeper parts of the trachea, while the second finer tube reaches only to about one-half of the first tube into the lumen of which it is inserted. The current of air in Kuhn's method turns, therefore, within the peroral tube at a level corresponding to the same part within the mouth of the pharynx. It is obvious that the action of such a current differs essentially from that of a current which reaches the bifurcation and has for its end the cutting out of the dead space and the returning of a strong air current along the tracheal walls.

Turning now to the practical applications of the method of intratracheal insufflation, I shall refer in the first place again to its use in exposing the thoracic cavity. As indicated above, we had in this regard quite an extensive experience. The safety and convenience of this method is here surely greater than that found in any of the best equipped cabinets for the differential pressure. The safety is greater, as there can be no danger of failure of respiration. As to the convenience, there can be no comparison, the method can be used anywhere, can be arranged at a moment's notice, and the man who attends to the bellows and the ether and who need not be an expert, can be kept entirely away from the operating table. As stated before, besides ourselves, Dr. Carrel and Dr. Elsberg worked with this method. Dr. Carrel made it the basis for the extension of his ingenious vascular surgical methods into new territories. Both gentlemen will probably report, themselves, their own experience.

Regarding the anesthesia we have already discussed above the advantages which this method offers to it. We have also stated above that by this method we succeeded in resuscitating animals dead from anesthesia, even after the heart had stopped for several minutes. It was further stated already before that in our experiments the paralytic effects of curara were effectively met by the intratracheal insufflation. Similar experience we had with the paralyzing effects of magnesium salts. I shall add here that in experiments which are now being carried on by Dr. Shaklee and myself in resuscitating animals dead from various other poisons, for instance, strychnine, morphine, carbon monoxide, the outlook is promising. For instance, in the case of a dog which received intravenously strychnine more than twice the fatal dose, the animal was thrice resuscitated by the intratracheal insufflation and thoracic massage, once even after the heart and the spontaneous respiration had stopped for more than ten minutes. Every time when the intratracheal insufflation was interrupted, the spontaneous respiration soon ceased and the heart stopped beating. Or cases of morphine poisoning might be cited with no respiration and no reflexes whatsoever in which circulation was kept going for many hours by the intratracheal insufflation. We are not ready for any report on our studies on these subjects, but I feel confident that in any case of poisoning, if discovered while the heart is still beating, intratracheal insufflation will be a great aid in rescuscitating the victim and maintaining his life. (In few experiments made with drowning intratracheal insufflation proved ineffective.)

Intratracheal insufflation will probably prove an efficient help in cases of temporary respiratory paralysis due to disease, for instance in post-diphtheritic paralysis of the respiratory muscles, in acute poliomyelitis, in respiratory paralysis due to a remediable intracranial pressure, etc. Volhard mentions a case of poliomyelitis in which the life was saved by keeping up the respiration for fourteen days by means of rhythmical compression of

*I may be permitted to speak here of the great credit which is due to Sauerbruch in the development of this interesting chapter of modern surgery. This seems to have been lost sight of in the oftentimes heated discussion over the merits of overpressure and underpressure. Not only was the idea of underpressure original and ingenious, but it is undoubtedly due to Sauerbruch's initiative that intrathoracic surgery has attained now such a promising aspect, and this merit will always be his, no matter which method will be found in the future to be the most useful one.

†Franz Kuhn, *Zentralblatt für Chirurgie*, 1908, p. 788.

the thorax. But I shall not discuss merely promising outlooks.

There is, however, one point more which I wish to bring out here. Our extensive experiments have, I believe, demonstrated the fact that *the entire trachea can be invaded without fear of causing damage to the pulmonary apparatus.* The various cavities and canals of the human body were invaded one after another by surgical ingenuity and persistence. The abdominal, cranial, and intrathroacic cavities are now open to the surgeon. The catheterization of either end of the gastrointestinal canal, the Eustachian tubes and the ureters belong now to the routine methods. The invasion of the trachea began already in the bronchoscopic studies. Our experiments have shown, however, conclusively that a tube may be introduced into the trachea and even into a bronchus with comparatively little precaution, and it may stay there continually for hours without causing any harm to the lungs and the bronchi. After all, the lungs are continuously in closer contact with the outside air than in any of the above-mentioned cavities and canals.

Shall the method of intratracheal insufflation which has been fairly well tested by animal experimentation be applied to human surgery? I do not consider it my province to come out here with such a definite advice. But I wish to urge upon the progressive surgeons who are not hopelessly tied to other methods to familiarize themselves with this simple method in operations upon animals. I am confident that they will then soon realize the great advantages which it offers in its application in human surgery. I am not in doubt about the future of the principle of this method, and it is the principle of the method I am interested in and not the minor details of the so-called apparatus. I risk even to prophesy that those who will have sufficient experience with it will soon employ it as a routine method for anesthesia in operations upon any part of the body.

AVOIDANCE OF APPARATUS COMPLICATING THE OPERATION — A PARAMOUNT REQUIREMENT IN THORACIC SURGERY.*

By WILLY MEYER, M.D.,

NEW YORK.

It has been after much hesitation that I decided to become a party to this symposium. For one thing, the necessity of open criticism of the work of a long time friend and valued colleague held me back. Moreover, he is on the staff of that institution, whose directors have enabled me by their broad-minded attitude to gain that personal knowledge of the question at issue, which mainly enables me to have to-day an opinion on the subject. Therefore, it is a matter of keen regret to me if I have to state here before you that Dr. Meltzer's proposition, as regards its applicability to the practice of intrathoracic surgery on the human being, appears to me in a different light than it does to him.

Again, though the proposition in general is surgical, its discussion must be carried on, partly, on physiological lines, and therefore for me, a surgeon, to take issue with Dr. Meltzer in his own chosen field, impressed me as rather venturesome.

*Read as a part of a symposium on thoracic surgery before the New York Academy of Medicine at its stated meeting, February 17, 1910.

There are other reasons that made me hesitate. A talk on apparatus did not appeal to me. I wanted to talk operations. I thought we had got beyond the apparatus stage. Our honored president has announced a symposium on intrathoracic surgery. But apparatuses are tools, not surgery.

Yet, inasmuch as apparatus cannot be dispensed with in the surgery of the chest, a full discussion of their merits and demerits may after all perhaps be a happy and timely occurrence to clear the atmosphere.

Again, I hesitated, because, having myself constructed apparatus, you might consider me biased, and I feared an impression might be caused to go forth from this symposium that antagonism exists between Dr. Meltzer's apparatus and mine, so that the one might work to exclude the other. Both ideas, should they exist anywhere, would be erroneous. The two apparatuses are not in the same class. They can exist side by side, and as for my mind, it is as open to-day as when I first approached the matter. As to the large body of surgeons of this country, so it is also to me entirely immaterial, whose apparatus will be "the" one; more likely there will be many. The only issue here, as in everything else in medicine, is the well-being of the patient.

Having thus endeavored to define my feelings with reference to the matter under consideration, permit me now to look at it from the point of view of science and go into *medias res.*

It is a curious fact that all those who have constructed differential pressure apparatus of, what Dr. Carrel calls[1] the classical type (an appropriate name for the purposes of this paper), started out with artificial respiration and used it as long as they were experimenting on animals; but when it came to applying to the human being the knowledge gained on the animal, they invariably abandoned artificial respiration, and went to the great trouble of developing their classical apparatus regardless of cost. Sauerbruch and Brauer abroad, and Green, Janeway, and Robinson in this country, have all gone through this experience. Of this type is my apparatus.

And it is also a fact that the use of that other type of differential pressure apparatus, constructed to save expense, and which for the purposes of this paper I would call the emergency type, remained in every instance confined to their sponsors. To this type belong the foreign devices of Tiegel, Brat-Schmieden, and Kuhn. The Meltzer-Auer apparatus is also of this type. They owe their existence partly to an actual emergency, as Tiegel's apparatus, or to the expressed intention to save expense, as Brat's apparatus, or to the endeavor to adapt an apparatus of the physiological laboratory, where animals are the patients, to the more exacting requirements of apparatus for surgery on the human being, as the Meltzer-Auer apparatus.

Now, it is also a fact that whatever real progress has been made within recent years in intrathoracic surgery on human patients, is due to, and stands entirely to the credit of, the classical type of apparatus which has been developed to a condition of reliability and usefulness, while none of the emergency type of apparatus has yet got fully beyond the experimental stage.

Both these types use differential air pressure, that is, as you know, a higher pressure within the lungs than prevails outside of the lungs, so that the lungs do not collapse after the thorax has been

opened. But they differ principally in this, that the classical type leaves the mouth free and accessible at all stages of the operation, while the emergency type encumbers the mouth with tubes, cannulæ, gags, and the like, or closes it with masks. They differ further, in that the classical type sails as close to nature as can be in retaining the physiological condition of natural respiration. The air supplied for lung ventilation is flowing continuously into a tank interposed as a cushion between the air supply and the lungs for their protection. The patient breathes from a large equalizing reservoir. Apparatuses of the emergency type send the afferent air directly into the respiratory tract and thus transfer to the same all the unavoidable vibrations, shocks, and inequalities in the flow of the air, using the lungs themselves as the pressure tank. Again, they differ in that the emergency type has definitely confined itself to positive differential pressure, while several of the classical type employ also negative pressure, and of late also mixed pressure. To some this may appear of little moment. But in the present state of our knowledge the position does not appear well taken that for operations on sick human beings one pressure is as good as another, that the effect of positive is in every respect the same as that of negative pressure.

Compared with the emergency type, the classical type of apparatus is cumbersome. Yet it is of that staunch, sterling reliability, which warrants us in entrusting unhesitatingly to it the patient's life. The emergency type, on the other hand, looks exceedingly simple and costs comparatively little. Yet, from the point of view of the operation, it is complicating. And that is what I would impress on you, that we must distinguish between *simplicity of apparatus* and *simplicity of operation.*

Operations requiring a wide open thorax differ from other operations in that for the same degree of safety they cannot be done without apparatus. For the surgeon that is a misfortune. The surgical part of chest work is exceedingly exacting. You are working on organs not at rest. The work has to be done deep down. The least slip in asepsis is sure death. It is work that requires complete concentration of the surgeon's mind and eye on the surgical side of the task before him. Divert his attention by any manipulation required of the apparatus, and the matter may become serious for the patient. Therefore, the surgeon should not permit himself to be deceived by the unassuming appearance of an apparatus. For him the question is, what kind of an operation will he obtain with that apparatus. For instance, at Dortmund, in Germany, they have tied a cheap galvanized iron funnel over the dog's snout, connected the tube to a source of compressed air, for inspiration, and, for expiration, have dropped a piece of rubber tube into a bucket of water. They opened the pleural cavity, and the dog lived. Would you take such risks with a patient? The apparatus certainly is the acme of simplicity; but what kind of an operation would you be likely to obtain with it on a patient debilitated by long weeks of sickness?

Let me emphasize once more: *Simplicity of apparatus,* and *simplicity of operation* obtained with that apparatus, are two separate and distinct matters. Only where both are combined in a method prevail ideal conditions for successful surgical interference.

Now, as this symposium to-night was originally intended as a discussion of Dr. Meltzer's paper, and inasmuch as it has been brought about by the apparatus for continuous intratracheal insufflation, it will be in order to examine into the Meltzer-Auer proposition, keeping in mind always that we do not examine it simply as a method and as an apparatus, but from the point of view as to how it affects an operation on the human being.

The Meltzer-Auer continuous intratracheal insufflation apparatus will be called herein, for the purposes of this paper for short, the "Blow-pipe Apparatus," inasmuch as a continuous current of air is kept blowing from a cannula at the bifurcation of the trachea all through the operation, and their continuous intratracheal insufflation method the "Blowpipe Method." In going through it, step by step, the attempt will be made to uncover the points complicating the operation, and it will be shown that its present simple appearance is solely due to its incompleteness, and that the apparatus will become more complicated before it can safely be used in operations on the human being.

History.—The beginning of the inquiry is naturally directed toward the question, to what extent is the blowpipe method new? Continuous insufflation has been practised by physiologists for two hundred and fifty years, they have used it and written much upon it during the last century, and surgeons have experimented with it since 1896. The French surgeon, Tuffier, used it at that time in Paris in intrathoracic animal experimentation.[2] In 1908 Robinson of Boston intubated through the mouth to the bifurcation of the trachea, sending in air under pressure through a cannula, and letting the exhaust escape to open air.[3] Kuhn of Cassel who has made intubation a specialty since 1895,[4] and in 1905 came out with a positive differential pressure method based on intubation,[5] closed at first the mouth air tight, but soon improved the method, and since 1908 introduces two tubes in one,[6] a narrow one for inbound compressed air and a wider one for the exhaust to open air. He, however, after much experimentation on the human being, found it best to keep the tube out of the trachea and to stop it at the upper end thereof just below the larynx.[4]

Both these surgeons, Robinson and Kuhn, each separately, but considered in conjunction certainly, have already done what it is proposed to do in the blowpipe method. I happen to know, though, that Meltzer developed his ideas independently. Meltzer told me that, having seen Sauerbruch at work in June, 1908, and later having witnessed some of my operations at the Rockefeller Institute, and seeing both pleural cavities wide open and the animal continuing to breathe, he had not trusted the evidence of his eyes and had gone into his laboratory to verify there what he had seen. Since then, I understand, he has been working on the matter.

The Meltzer-Auer Apparatus and How It Works.—Let us next examine into the characteristics of the blowpipe method. A cannula is introduced through the mouth into the trachea and pushed in as far as the bifurcation. Meltzer and Auer found[7] that the diameter of the cannula must be two-thirds of that of the trachea, which, when figured out, is about the same as saying that the cross-section of the cannula and the cross-section of the ring-shaped space, remaining between cannula and trachea, must be of equal area. In adults the trachea has a diameter of from 7/16 to 11/16 of an inch. Therefore, the cannulæ, figured as above, should be 5/16 to ½ inch thick, and the width of the ring space 2/32 to 3/32 of an inch (assuming the trachea

as of circular cross-section, which is near enough for present purposes). This ring space we will call herein "the flue." At its free end the cannula is connected with a source of compressed air and an ether bottle. A mercury gauge and a by-pass around the ether bottle are connected in, also two outlets to open air, one between air-compressor and gauge, and one between gauge and cannula.

Assume now the cannula in place in the trachea, and the air flowing, passing through the ether bottle on its way. A new mouth has been established, so to speak, at the bifurcation of the trachea, whereby is eliminated a part of the dead space which is the sum total of the air passages from larynx to alveoli. The patient breathes spontaneously. Inspiration takes place at the new mouth, where he inhales the compressed air coming from the cannula, and expiration takes place by way of the flue through the old mouth.

Intubation.—It is not to be supposed that the cannula will stay in the exact center line of the trachea and leave between its outside and the mucous membrane the theoretical air space, but in the course of the operation it will touch the membrane soon here and soon at another point, thereby irritating the membrane and causing secretion of mucus, if not capillary hemorrhage. In his very extensive use of intubation on the human subject Kuhn found excessive irritation of the trachea and very considerable secretion of mucus if the tube was pushed down into the bronchus or down to the bifurcation, or even only one inch below the larynx. He also found strong secretion of mucus in the larynx, if the intubation did not succeed the first time.[4]

Meltzer took part in the discussion of a paper on laryngeal intubation at the International Congress at Berlin in 1890, and there stated that with the glottis open, as in intubation, aspiration of foreign matter into the lung was impossible.[8] That may be correct as far as the old outside mouth above the glottis is concerned. But here the conditions are different. A new inside mouth has been established below the glottis, where a continuous flow is kept up of inbound compressed air. At that point inspiration takes place, and when it does set in, whatever mucus has collected there may be either aspirated or forcibly blown into the lung. It is claimed for the blowpipe method that the outbound air, which flows up the flue along the tracheal wall, will dry up the mucus, so that there would be none there to be aspirated; but, whether that will be the case with people having bronchial affections, remains to be seen. They may secrete more mucus and may secrete it more rapidly than the air can dry it up. In any event at the beginning of the operation secreted mucus will gather at the end of the cannula, because the drying up process will take some time to become effective, while the irritation of the membrane and secretion of mucus are immediate and coincident with intubation. Therefore, at the very outset mucus is liable to be aspirated, and the damage may have been done, and the foundation for a subsequent pneumonia may have been laid, before the surgeon really gets to work.

Again, intubation requires experience. An experienced intubator ought to succeed in getting the tube in place without causing blood to flow; but what about the average intubator? It is essential in intubating to keep exactly to the center line. The index finger is pushed away in and used as a guide; but young assistants frequently will not feel the larynx. Then, there is danger of deviating from the center line and of pushing the cannula into the valleculæ between the epiglottis and the root of the tongue; or it might glide over the rim of the larynx into the esophagus; and if that is not noticed in time, the stomach will be blown up. Even after the epiglottis has been passed there is still danger of getting the cannula into the sinus pyriformes or into the Morgagni pocket (Kuhn). Thus it will be seen that for intubating human beings an experienced assistant is required in every instance.

Difficulties of Intubation and Contraindications.—Not infrequently the root of the tongue is found to be so thick that considerable difficulty is encountered in getting over it. Kuhn found it in one instance physically impossible to reach the larynx, and the same happened to Eiken in cases of dyspnea and heart disease.[9]

Intubation is contraindicated in various affections of the larynx and of the trachea, and the blowpipe method is excluded in cases of goiter, where the trachea has still sufficient lumen for the cannula, but no space remains for the flue. Kuhn also mentions cases where the tube was not tolerated by the narcotized patient and had to be withdrawn after it had been in place for some time. Therefore, it will be seen that the blowpipe apparatus is not all-sufficient, and that one needs another differential pressure apparatus without intubation in addition to it in order to be prepared for all possible occurrences.

Comparison of the Meltzer-Auer and Kuhn Methods.—Mechanically Kuhn's is a better arrangement. He provides a narrow lumen for the high-pressure inbound air pipe, and a wide lumen for the low-pressure outbound air pipe (exhaust), the two pipes forming one tube. Thus no back pressure can be set up in the exhaust pipe. Moreover, this exhaust pipe being metal, can be cleansed of mucus, with a wire brush, while in place.

The blowpipe method provides equal lumina for high and low-pressure channels. The low-pressure air outlet (exhaust) is that long, narrow flue formed by the outside of the cannula on one side and the mucous membrane of the trachea on the other. It is inaccessible during the operation; but even if it were accessible it could, of course, not be cleansed with a brush, because of the mucous membrane, but only by suction, requiring additional intubation.

Again, Kuhn stops at the upper end of the trachea, a definite point. In the blowpipe method it is intended to stop at the lower end of the trachea; yet, *in praxi*, it can here not be determined just exactly where the end of the cannula is located. Meltzer's rule is: "Push in until you meet a resistance, then pull back two inches." Whether that leaves the end of the cannula in the bronchus or in the trachea, is not known.

For the blowpipe method, the providing of two separate channels in the trachea is claimed as an advantage, which, of course, Kuhn has not, because he stops at the larynx. The point of destination of inbound air, after it has passed the larynx, is not the bifurcation of the trachea, but the alveoli, and if two channels were needed or were advantageous in the trachea, they would be much more so in the bronchi and the bronchioli. To subdivide these is, of course, an impossibility. Therefore, to provide two channels only as far as the beginning of the

bronchial tree appears to be a half-way measure.

Intubation or Anesthesia First?—As a rule, the patient would likely first be anesthetized in the old way; then be intubated, and anesthesia then be continued by tube. But Kuhn has frequently intubated first and anesthetized afterwards.

Anesthesia.—We will next consider the anesthesia effected by way of the cannula. Here it is again Kuhn of Cassel, who for the last seven or eight years has practised pulmonal anesthesia.[10] Two drawbacks stand out prominently therewith: first, intubation requires deep anesthesia; second, the quantity of ether administered cannot be properly controlled. Lotsch of Berlin, who operated with Kuhn's latest differential pressure method with open exhaust, says on this point that by the exhaust current of air the narcotic is driven out, and only during inspiration does some of it get into the lung; that consequently a large quantity of ether is required, and how much of it comes to absorption cannot be definitely known.[6] The same holds good for the blowpipe method.

Kuhn, in 1905, demonstrated pulmonal application of the anesthetic by intubation to Czerny of Heidelberg, Trendelenburg of Leipsic, and Angerer of Munich, visiting each of these surgeons individually. But I have not heard that they have taken kindly to it for use in thoracic surgery on the human subject, or that its use for that purpose has spread.

Respiration Under Various Conditions.—Before entering into the discussion of the characteristics of the respiration in the blowpipe method, let us stop just a moment to review the character of respiration under other conditions. "Our normal respiratory movements consist of an active inspiration followed by a passive expiration" (Howell).[11]

"During the respiratory expansion of the lungs inflation of the organ is performed purely by variations in tonus without any actual distention by increase of air pressure . . . The muscles which dilate the thorax do not contract until the lung begins to relax; they then contract in proportion to the relaxation of the tonus, and thus bring about filling without distention. The muscles relax again only when the tonus of the lungs is restored and gives the signal for expiration. Both processes are controlled by a reflex innervation, a far-reaching synergy, so as to preserve precision in the cooperation of the various parts, . . ." (Hoffman).[12]

That is nature's apparatus. When that apparatus failed, recourse has been had since time immemorial to intermittent insufflation. Our modern representative of that type is the Fell-O'Dwyer apparatus for artificial respiration. In this method the natural physiological condition of respiration is reversed. It results in passive inspiration and active expiration.

In the differential pressure method as practised to-day with the classical type of apparatus, either atmospheric pressure or less than atmospheric pressure weigh upon the outside of the lung after the thorax has been opened. Inside of the lung the intraalveolar and intrabronchial pressures are increased over and above the outside pressure by an amount sufficient to overcome the elastic retractility of the lung tissue and to balance it in the expiratory position. The pressure required to accomplish that is maintained over the mouth of the patient. Respiration takes place spontaneously, according to his physical requirements, and inspiration, therefore, being coincident with the tonic contraction of the muscles of thorax and diaphragm, is active. Expiration, however, is not passive. The contraction of all the expiratory muscles is required for expiration against, and for the overcoming of, the differential pressure. Therefore, expiration is active, too; that is to say, in the differential pressure method both inspiration and expiration are active.

Respiration with Continuous Intratracheal Insufflation.—Now what do we find in the blowpipe method? The source of compressed air has been connected up to the free end of the cannula, and insufflation through the same at the bifurcation of the trachea begins. The air is supplied continuously by means of a bellows; but the breathing is intermittent; it is the spontaneous action of the lung, and the bellows only serves the purpose of delivering enough air to make the lung stay distended with an open thorax. Breathing is slow, and a regular rhythm is maintained: inspiration, expiration, interval, inspiration, expiration, interval, etc.

The pressure prevailing over the new mouth, that is, at the end of the cannula, determines the character of inspiration and expiration. This is the same as in any positive differential pressure apparatus of the classical type, except that here the new inside mouth has been substituted for the old outside mouth, and except for the interval, during which, I understand, lung ventilation, not obtainable with apparatus of the classical type, is claimed for the blowpipe method. Let use see whether there really is an interval, for, if there is not, then, of course, all claims for the same will fall also.

I asked Meltzer what the pressure was at the bifurcation, and he told me he did not know, so that I am in the dark on that important point. But the pressures can be approximated in this way: the thorax being open, human lungs would collapse unless the inside pressure were held up to at least 5 mm. Hg, 3 mm. being pneumothorax and 4 mm. being still dangerous. But as the flue from the new mouth to the old mouth leads to open air, it acts as a leak, it lowers the pressure. The cross-sections of both channels being equal, an average pressure between open air (that is, no mm. Hg, or zero pressure), and the pressure coming from the cannula must exist at the new mouth, and if the lung pressure is to be 5 mm., then the cannula pressure must be 10 mm. in order to yield an average of 5. Throughout the operation it is not permitted to sink below that level, except for artificial respiration. Now inspiration takes place.

When expiration sets in the air comes from the bronchial tree under 5 mm. pressure plus the physiological expiratory effort of at least 3 mm., therefore under a total pressure of not less than 8 mm. At the bifurcation of the trachea the outgoing tidal flow meets the air coming under pressure from the opposite direction through the cannula. The direction of flow of the air coming from the lungs prevails, and both quantities together run outbound into the long, narrow flue which, as stated, is only from 2/32 to 3/32 of an inch wide and, furthermore, contracted at the glottis, also more or less clogged with soft and dried up mucus. Thus, what is left of the trachea is too narrow a channel for the total quantity of air to pass out unchecked. A back pressure is set up in the flue against which expiration has to be effected. (The open side outlet on the cannula prevents its becoming excessive.) The back pressure will last until the thorax has reached its position of rest. The result of this is

that an active expiration takes place, and, further, that when the excursion of the thorax has come to an end, which ordinarily would be the end of the expiration, the lung has not yet come to the end of its expiration, but continues to collapse during the now following interval. For, when the pleural cavity is open, the movements of the lung depend not only on the action of the ribs and diaphragm upon them, but more particularly on the intratracheal pressure. The rate of progress of the continuing collapse of the lung is therefore in conformity with the gradual falling off of the pressure at the new mouth, while the average pressure is reestablishing itself between the cannula pressure and open air, preceding the next inspiration.

Consequently, it seems to me, there is no interval at all existing, but only a long drawn out expiration, of which the apparent interval is a part. The current of air during the apparent interval is from the lung towards the flue and not from the cannula into the lung; in other words, during the apparent interval the air flows out of the lung and not into the lung. Fresh air reaches the alveoli in the blowpipe method, therefore, only during inspiration, the same as in the classical type of apparatus. As already shown, inspiration and expiration are active, so that all the characteristics of the breathing in the differential pressure apparatus are present, without any additions or omissions, and, consequently, the blowpipe method appears to be a positive differential pressure system.

Dynamic Diffusion.—The effect of the eddy-currents of air which, it is claimed, are set up in the blowpipe method at the bifurcation has been called by Meltzer dynamic diffusion. Of itself it seems to be insufficient to properly arterialize the blood.

Talking about the lung ventilation by the blowpipe method of a curarized dog, Meltzer and Auer say:[7] "If the glass tube" (meaning the cannula) "is a little too wide or a little too narrow in relation to the lumen of the trachea, the lungs acquire easily a slightly cyanotic appearance. But then, a disconnection of the tube from the pressure bottle for two seconds, which means a momentary collapse of the lungs, restores immediately the pink color of the lungs, and a repetition of this procedure once every three or four minutes is sufficient to maintain the life of the animal in a satisfactory fashion for many hours, although, under these circumstances, the blood pressure is subject to frequent variations."

That is equivalent to saying that cyanosis will always occur, because the diameter of the trachea cannot be measured before the operation, and, consequently, only by the merest accident can the cannula be of just the right width, and as a general rule will be what Meltzer and Auer found it, a little too wide or a little too narrow.

On a curarized dog, the excursions of the thorax and the diaphragm cease altogether; there is neither inspiration nor expiration, and consequently almost complete stagnation of air in the lungs, except for the slight vibratory movement set up in the lung by the beating of the heart. This, then, is where dynamic diffusion could show its sufficiency; but once every three or four minutes the lungs must be deflated, the carbonic dioxide must be forced out. Dynamic diffusion must be assisted by respiration, for that is what deflation and reinflation mean.

Again, Meltzer's statement that by means of continuous intratracheal insufflation a dog cannot possibly be killed by ether, is proof positive that there is only a periodical exchange of gases going on between the main bronchi and the alveoli, for the insufflation of ether is as continuous in the blowpipe method as the insufflation of air. Therefore, if all, or most, of the ether reached the alveoli, the dog would certainly be killed. A great deal of it must, from where it leaves the cannula, be going right back up the flue, without taking any effect whatever, which means that a great deal of the air blown in must also be going the same way without, from the standpoint of lung ventilation having done any good.

By the courtesy of Dr. Meltzer I had an opportunity to operate by the blowpipe method on a dog, he himself very kindly superintending and directing the manipulation of the apparatus by his own man. It worked well on the animal. All through the operation artificial respiration was performed, at the average rate of 6 per minute, and dynamic diffusion was not relied upon. Simultaneously the number of spontaneous respirations of the animal decreased to about 10 per minute.

Apnea.—There is good authority for the assumption that the decreased number of spontaneous respirations per minute in the blowpipe method is not due to the altered chemical composition of the blood, in which it has an over-supply of oxygen and only about one-half its normal supply of carbon dioxide (apnea vera), a composition which dynamic diffusion is supposed to bring about, but that it is due to vagus reflexes (apnea spuria).

Luciani and Bordoni experimented[13] in 1887 on birds, using continuous tracheal insufflation with open thorax. The air was sent in by way of the trachea, through the lungs and out to open air from the abdominal air bags of the birds. So there was real circulation of air and consequently real ventilation. They found, among other features, firstly, apnea setting in coincidently with the beginning of the ventilation, before there had been time to wash out any CO_2; secondly, no apnea when the vagi had been severed; thirdly, imperfect apnea when oxygen was used for ventilation instead of air and the vagi were intact. Therefore, it may well be that the slowing up of respiration in the blowpipe method is not due to beneficial effects of dynamic diffusion upon the chemical composition of the blood, but rather to its harmful influence upon the nervus vagus, harmful because vagus reflexes affect not only the lungs but also the heart. I have no means of knowing what experiments may have been made by Meltzer to elucidate these conditions. Certainly, full light upon them is needed for the use of continuous intratracheal insufflation on human beings.

Inbound Air.—Nor is the cutting out of the upper one-fourth of the dead space harmless.

Bloch of Freiberg, who has made a painstaking investigation of the physiology of nasal breathing,[16] finds the rise in temperature of the inbound air between nostrils and pharynx, that is only about half the distance cut out in the blowpipe method, to be 5/9 of the difference of its temperature and blood heat, on an average about 15° C. (27° F.). The temperature of inbound air at the pharynx is uniformly about 25° C. (77° F.) for nasal breathing. For mouth breathing the warming up averages

*This view is further confirmed by an experiment mentioned by Dr. Meltzer in his paper, read on February 17 inst. He blew finely powdered charcoal into the afferent air and found very little of it in the alveoli, but most of it deposited on the walls of the flue.

about 6° C. (11° F.) between teeth and pharynx. At the same time the air is humidified to 2/3 of the point of saturation at the higher temperature. Between pharynx and bifurcation the temperature is further increased.

The velocity of the afferent air must also be taken into consideration. The cannula has only one-half the lumen of the trachea, delivers, therefore, only one-half the quantity of the air ordinarily inspired, if the air flows in the cannula with the same velocity that it normally has in the trachea. A larger quantity can be obtained only by an increased velocity. In order to obtain the normal tidal flow the velocity would have to be doubled. Probably the velocity is somewhere between normal and twice normal. The air flows, therefore, with greater velocity than in ordinary breathing, and, in addition, it is not only not tempered, but is laden with the cold vapors of ether. In this condition, at the point where it comes from the cannula, it strikes a point that physiologically is little adapted to be so struck, and not for a moment, but anywhere from one hour and longer continually.

Pressure.—During my above-mentioned operation with the help of the blowpipe method on a dog a bellows was the source of air compression. My assistants made the following observations: The pressure fluctuated continually on a mercury gauge from about 12 mm. to 20 mm., with occasional spurts to 25 mm. and over, and falls to zero from five to eight times per minute, whenever the attendant took his thumb off the opening of the side-tube. The fluctuations were so rapid that it was impossible to read the gauge accurately. These great fluctuations were not communicated unchanged to the trachea, because between gauge and trachea another side-tube had been arranged which led to open air and could arbitrarily be closed, more or less, with a thumb-screw. The shock of the fluctuations was thus somewhat cushioned, but the fluctuations themselves were nevertheless reproduced inside of the trachea as they occurred, though between what limits is not known. But it is known that very slight changes in intrabronchial pressure result in very great changes in blood pressure[19] and a careful determination of just what is here going on in the trachea would be useful.

It is true that surgeons have demanded that their intrathoracic apparatus should enable them to make quick changes in intrabronchial pressure. Kuettner wants this for surgical reasons,[14] and Friedrich for diagnostic reasons.[15] But all of these surgical demands require sustained, not fluctuating, pressure, and gradual sustained variations of pressure, changes quite unattainable with bellows.

Another feature of the blowpipe method that must necessarily be changed for its use on the human being is the present way of raising the pressure in the lung when closing the thorax, so as to fill it and bring it back into contact with the chest-wall. The physiological condition existing before the thorax was opened is thus restored, and the wound can be fully closed without danger of pneumothorax.

In order to obtain this result in the blowpipe method, the animal is simply choked by closing with the hand what is left of the trachea, that is, by closing the flue, the channel of the outbound air, and leaving open the cannula, the channel of the inbound air. The lungs flare up and are physically distended. In order to avoid the danger of overextending them the choking process cannot be maintained very long, but the hand must be taken off and the pressure be interrupted. During this interruption the lungs go down and produce again just what it was intended to avoid, the air space between pulmonal and costal pleura which was present while operating.

But that is not all. It will be remembered that the animal is breathing spontaneously. If by inadvertence or inexperience the interruption of the choking should not be carefully timed in relation to one respiration, or, if the choking should have to extend over several complete respirations and should not be interrupted properly, then an expiratory effort may take place against the closed outlet of the trachea. A true Valsalva, here still increased by the continuous inpumping of air, will then occur, one of the two conditions: "by which the respiratory fluctuations of intrathoracic and intraabdominal pressure will exert their extreme influence upon the circulation of the blood or rather upon its entering and leaving the thoracic cavity. If after a deep inspiration the glottis is closed and then a strong and persistent effort is made at expiration, the pressure thereby exerted upon the heart and the intrathoracic blood vessels can lead to a momentary stoppage of heart actions and circulation. The veins of the throat and face swell up, the capillaries of the lung are emptied, the aortic system is overloaded, the heart sounds cease and the arterial pulse disappears" (Luciani).[13] Luciani adds this warning: "The experiment is not without danger, especially for old people, and for those whose cardiovascular system is not strong or of normal function."

In an exploratory thoracotomy on a patient, performed recently at the German Hospital, the pressure stood for almost fifteen minutes at 12 mm. Hg, when closing up. Certainly, the patient could not have been choked for a quarter of an hour. Again, the pressure was applied after the thorax had been almost completely closed, when the lungs were no longer visible. What guides are there under such circumstances in the blowpipe method to indicate that sufficient pressure has been applied, but not too much? In the blowpipe method it is not known what pressures prevail in the trachea. No means are provided for gauging them. They are uncontrolled and of accidental magnitude; their regulation, such as there is, is entirely by guesswork. It would certainly be desirable to have at least their upper limit accurately determinable. For, the lungs can be overextended, and if that should happen and be continued for a quarter of an hour, interstitial emphysema would be the unavoidable consequence.

It will be said that so long as the thorax is open the appearance of the lung before him, and not the gauge, tells the surgeon what to do; and in the end it will probably amount to the same thing, whether to the attendant, manipulating the air, the one calls out, "More, more," and "Less, less," or whether another simply commands "Six," or whatever other number of millimeters may be required; both will get what they want. But the latter surgeon has the advantage, after he has once observed the behavior of a particular lung under various definite pressures, that in the course of the operation, by a short word of command, he can get instantly what is required at that moment, while the other one, using the blowpipe method, will have to go again through his more and less, every time he needs a change. Moreover, in keeping his records

of, and in communicating to others the results of, his operations, the one employing the blowpipe method cannot be scientifically accurate, but can talk only in generalities.

The Probable Appearance of the Final Continuous Intratracheal Insufflation Apparatus.—By the time the blowpipe apparatus is perfected for use on the human being, it will quite likely look no longer so simple as it does at present in the shape in which it is applied to animal experimentation. A number of features will have to be changed and others will have to be added. The cannula down the trachea cannot remain a rubber tube, but must be made of metal, probably with a removable mandril and a special mouthpiece. The outfit for anesthesia cannot be left quite so remarkable in its simplicity. To send the inbound air directly through the ether bottle, where it picks up an uncontrolled amount of vapor, will hardly do. It is bad enough that it cannot be definitely stated, how much of the ether sent in is absorbed by the blood. But if, in addition, it is not known, either, how much ether per minute is regularly sent in, that, to me at least, appears risky. Suppose something should happen during the anesthesia, how would it be possible to prove that an overdose of the narcotic had not been administered? Meltzer says that cannot happen with the blowpipe method. But the unexpected always happens, and even if a dog cannot possibly be killed by uncontrolled amounts of ether, maybe that not all human beings are equally resistant, and that some of them will succumb. As Tiegel says: "Dogs do not drink, nor do they smoke or keep late hours." Every surgeon will, without further argument, agree that provision must be made, when operating on the human being, for a controlled anesthesia, as far as that is obtainable in the blowpipe method. In addition, an oxygen tank will probably be needed, which will add to the complication of necessary connections. Next comes apparatus for the warming up and humidifying of the inbound air, and perhaps, also, a filter to take out the dust. Then a tank, etc., is needed between the bellows and the lung for equalization of flow of air. The muscular effort of the foot of the man working the bellows is not a sufficiently reliable governor, nor is what is left of the trachea a sufficiently large receptacle. The bellows itself is an unreliable mechanism. Matas has spent years in experimenting on pumps to take the place of the bellows in his insufflation method for intrathoracic work.[17]

Again, reserves are needed and substitutes. They should be provided in such a way that they do not entail undesirable duplication of parts. They are required, because the operation must not be interrupted, if something mechanical should fail to work properly during its course. Such happenings usually occur at critical moments, and, if it then is necessary to hunt first for the seat of the trouble, the patient will probably be dead before it is located.

Reserves of the Universal Differential Chamber.—In my universal differential chamber,* if something should go wrong with the machinery, the two gauges, one for vacuum and one for pressure, indicate at once just what has happened. A quick turn of valve handles, consuming less time than it takes to tell about it, and everything is serene again. Ordinarily the blower and the suction pumps are running at the same time. Should the blower be short-circuited, and thus the positive pressure have been cut out, then we continue with negative pressure. The suction pumps for the latter are divided into two independent units, each set in motion by another source of current, and thus each a reserve for the other one. Should, at another time, instead of the blower, both of these suction units fail to work, destroying the partial vacuum, then we continue with positive pressure. Thus the machinery producing the negative pressure is a reserve for that producing the positive pressure, and vice versa. Should all power fail at one and the same time, then there is still a hand-driven blower in reserve to fall back upon. That something should happen to my chamber proper, is almost inconceivable. It cannot happen to the iron work. A tear in the balloon material could hardly be detrimental, because there is, firstly, enough air delivered to take care of a leak, even a considerable one; secondly, the exhaust pipe can by means of the valve be closed or partly closed, thus turning the leak into an exhaust opening, and, finally, rolls of widest adhesive plaster are always at hand with which to close a tear.

Such security as I have in my apparatus appeared to me worth paying for. It makes me forget that I am working with apparatus.

Some Advantages of Continuous Intratracheal Insufflation.—The blowpipe apparatus shares the advantages of its type of positive differential pressure apparatus, namely, that it can be used in the same operating room, no matter how cramped, where the surgeon performs his other operations, and also upon the same operating table. Both these advantages are more apparent than real, because, firstly, as regards the table, for most intrathoracic work a special table is required, one that cannot only be turned around its transverse axis (Trendelenburg posture), but also around its longitudinal axis;[15] and, secondly, as regards the operating room, our regular ones are usually so crowded with the daily routine work that there would hardly be sufficient time left to use them for intrathoracic operations requiring special paraphernalia. It will certainly be much better to have additional facilities for intrathoracic operations, and to have not only one, but two additional operating rooms, one for aseptic and one for septic operations, each with a separate outfit.

Again, the blowpipe apparatus, for animal experimentation, composed of rubber tubes and glass and a bellows, might suggest the idea that it could easily be carried in a grip and be taken to the residence of a private patient. But, unless the patient is positively untransportable, he should always be taken to a hospital, because the asepsis required in intrathoracic operations is so exacting that it is almost impossible of attainment under conditions ordinarily prevailing in residences. So this advantage, too, is more apparent than real. However, a real advantage of the blowpipe method, one which it also shares with others of its type, is the freedom of movement it allows the surgeon when he has to operate in the upper region of the chest. In the classical type of apparatus the necessary means for air-tightening around the neck of the patient make that class of operations somewhat unhandy, though quite feasible. I contemplate using the blowpipe type on occasion in such cases, when it has been perfected.

Some Further Disadvantages of Continuous Intratracheal Insufflation.—Frequently the surgeon will find himself facing an operation, where he knows beforehand that the pleura is in danger of being torn. If an apparatus of the classical type is

*See *Jour. Am. Med. Assn.*, 1909, page 1978.

at hand, it is in such cases a great nerve tonic for the surgeon to operate with the apparatus, but, of course, so long as everything goes well, without differential pressure. Should danger arise, the command, "Pressure, 5!" (meaning 5 millimeters) will end it instantly. The operation is then continued under differential pressure. With the classical type of apparatus the operation proceeds unaltered so long as the pleura remains intact. With the blowpipe method it means intubation all through the operation, or else, intubation with an open pleura.

It can also happen that the extent of the disease proves more far-reaching than anticipated, and that it is found to involve the pleural cavity. With the classical type the apparatus is in that event simply moved up to the operating table, or vice versa, and the head of the patient is put through the opening into the pressure apparatus; it is only necessary to move the patient longitudinally on the operating table. In the blowpipe method it means intubation during the course of the operation.

Another and a very important disadvantage of the blowpipe method is this: that it cannot be used in the after-treatment, a consideration proving, what was pointed out once before, that the blowpipe method and apparatus are not all-sufficient, but that other differential pressure appartus would be needed along with it.

Classical Type Apparatus All-sufficient.—It should be clearly understood that there is nothing in thoracic surgery, however extreme, attainable by means of the blowpipe method, which cannot also be done with less complication and greater safety with the classical type of apparatus. Reference is here had to operations in which the thorax being widely opened, the diaphragm and ribs can hardly act on the lungs.

As early as 1904 Sauerbruch published[18] results of experiments performed in his first negative chamber, in which he gradually resected the entire thoracic walls, and the animal lived. He has also in his negative chamber cut away, on a rabbit, all the muscles of thorax and abdomen, including the diaphragm, that in any way affect the lungs. According to Hultkrantz,[13] the excursion of the thorax contributes about two-thirds, and of the diaphragm one-third to the quantity ordinarily inspired. The lungs stood motionless and distended, like inflated bags, without any active or passive movement. Functionally they were entirely cut out. In this physiological experiment, if it is intended to keep the animal alive for some time, the lungs are slowly deflated and slowly reinflated, in the classical type of apparatus, by use of the means provided for artificial respiration.

But these extreme cases are governed by entirely different considerations, viz., the reflex effects of the finest sensory fibers, and these considerations have no connection with apparatus and are, therefore, identically the same for all the types, classical, emergency, or otherwise. These reflexes, probably brought about by the sudden contact of the pleura with open air, cause a rapid sinking of the blood pressure and acceleration of the pulse, and if not correctly handled, may lead to immediate death.

In order to be able to speak from my own knowledge, I have performed recently at the Rockefeller Institute in my chamber, which, as stated, is of the classical type, two operations of that character on dogs. I have excised the sternum and then cut transversely, between the fifth and sixth ribs, to within one inch of the spine on either side. Thus the thorax fell apart in four directions, and there was a wide space between it and the lung. The first time I made the intercostal division all at once. The thorax fell apart and exitus followed soon.

The second time, after excising the sternum, I performed the intercostal incision slowly, a few inches at a time, to within one inch of the spine on either side, at the same time putting the animal under deeper narcosis to exclude, or at least minimize, the pleural reflexes, and also performed artificial respiration with the apparatus at the rate of two per minute, between the limits of 15 mm. and 2 mm. Hg.

In parenthesis, attention is called at this point to the advisability of avoiding in such cases the lowering of the pressure to 0 mm. Hg (atmospheric pressure), in other words, of avoiding the complete destroying of the difference in pressure between the inside and the outside of the lung. The collapsing of the lung is not sudden, but rather slow under the gentle pressure of the elasticity of the lung tissue. Therefore, a sudden reduction of the intrabronchial pressure to zero and subsequent immediate restoration of the pressure to its previous level, as practised in the blowpipe method, has little beneficial effect upon the lung, but a very harmful effect upon the heart.[19]

If the lung is really permitted to reach the pneumothorax stage, the danger arises which Hermann has pointed out,[20] that the smallest bronchi collapse and stay collapsed, when the lung is put again under pressure for reinflation, leaving large spots of the lung atelectatic. The danger is obviated by retaining some difference in pressure.

Reverting now to my physiological experiment, the only one I have taken the time to indulge in. The animal lived. When sewing up, thinking all danger past, I stopped the artificial respiration, and was working with a constant differential of 7 mm., the animal breathing spontaneously, when it suddenly collapsed. Gums white, respiration nil, heart beats ebbing away. Artificial respiration, 4 per minute; heart massaged. No anesthetic. During the artificial respiration, the epiglottis was well drawn forward. The animal came completely around, and left the table alive. Naturally, such far-reaching divisions of the thoracic walls will rarely happen in operations on humans.

Surgery Ready Now for Intrathoracic Work.—Like everything else, apparatus for thoracic surgery is an evolution. For one hundred years many minds have been busy elucidating the intricate relations between lungs and heart, between respiration and circulation, upon which such apparatus necessarily must be based. Meltzer has apparently thought that by going back fifteen years and starting over again from where the art was at that time, he could succeed by thus turning back to first principles in going his own way, and find a new solution of the problem.

He has given us only an additional endorsement of the differential pressure principle, and, unfortunately for him, his apparatus is beset with the troubles of fifteen years ago, troubles which later thinkers had succeeded in ferreting out and had managed to avoid in their apparatus. Gradually, step by step, the classical type of apparatus has been developed and is now in such a state of perfection that the life of humans can be entrusted to it without hesitation. Green and Janeway, also Robinson, myself, and, maybe, others on this side of the Atlantic, of whom I do not know, have such

apparatus. We are ready for work and have done work on the human subject with our apparatus. There is absolutely nothing in the way of intrathoracic operations that is excluded from the sphere of this classical type of apparatus. Exploratory thoracotomy can be performed to-day with the same degree of safety as exploratory laparatomy, and if proper preparations have been made, can be promptly followed up with the indicated operation.

Conclusions.—1. Intrathoracic surgery cannot be done properly and safely without differential pressure apparatus.

2. Negative and positive differential pressure are, it seems, not identical in their effects upon sick human beings. Whether they are or not, must still be established, and indications be found for their use. This is rendered feasible by the universal differential pressure chamber.

3. Continuous intratracheal insufflation as practised by Meltzer and Auer appears to be a positive differential pressure system.

4. Its weak points are the use of the human trachea as a vital part of the apparatus; the possibility of aspiration at the beginning of the operation, with subsequent pneumonia, and of interstitial emphysema at the end of the operation, as a consequence of its employment; also the required deep anesthesia. Intubation reaching below the glottis has been found to give rise in the human trachea to immediate copious secretion of mucus.

5. Sudden complete interruption of the prevailing differential pressure, followed immediately by its equally sudden restoration, as practised in continuous intratracheal insufflation, is liable to hurt the human heart. Very slight changes in intrabronchial pressure give rise to very great changes in blood pressure.

6. Continuous intratracheal insufflation apparatus is not adapted for use in the after-treatment, nor is it otherwise all-sufficient. Those employing it need some other type of differential pressure apparatus in addition to it, in order to be prepared for every emergency.

7. The safest method of general anesthesia is the one used in our every-day surgical work, the inhaling of the narcotic with spontaneous respiration and with mouth and throat left unencumbered. This method is the one used in the larger differential pressure chambers.

8. In surgery, when entrusting human life to the safe working of mechanical apparatus, it is wise to have substitutes on hand, in order to be prepared for accidents. In continuous intratracheal insufflation everything depends, at present, upon the one cannula and the patency of the trachea.

9. As far as the patient is concerned a differential pressure system leaving mouth, throat, and trachea unencumbered, appears preferable to one requiring intubation.

EXPERIMENTAL INTRATHORACIC SURGERY BY THE MELTZER AND AUER METHOD OF INTRATRACHEAL INSUFFLATION.

By ALEXIS CARREL, M.D.,

NEW YORK.

During the past few months I have performed some operations on the thoracic viscera by using the method of Meltzer and Auer. The purpose of these experiments was to find out new methods for the future surgery of the heart and of the aorta. I attempted to improve the general technique of intrathoracic operations and to develop procedures which could be used in the treatment of aneurysms and of certain heart diseases. This study was rendered possible to me by the method of Meltzer and Auer. In the extensive operations on the aorta and the heart it is necessary that every detail of the technique be adapted to the conditions created by the opening of the pleural cavities, the handling, and the temporary disturbance of the functions of the organs. The respiration stops often whether spontaneously or under the influence of thoracic dislocation. In its extreme simplicity, the apparatus of Meltzer and Auer does not modify at all the ordinary operative conditions. Besides, it presents the very important advantage of permitting the respiratory exchanges to continue, even if the respiratory movements have stopped or become inefficient.

The apparatus I used is composed of only a foot bellows, a rubber tubing connected with an ether bottle and a manometer, and a small intratracheal catheter.

I tested, at first, the method in some comparatively simple operations such as resection of pulmonary lobes, extirpation of a segment of the middle part of the esophagus followed by circular suture, and dissection of the mediastinum by opening of the two pleuræ and the pericardium. The chests of a few animals were opened by a half circular transverse incision, with section of the sternum. The upper and lower parts of the thorax were strongly retracted in such a way that the ribs and the diaphragm could hardly act on the lungs, which were half inflated and almost motionless. Nevertheless the respiratory exchanges remained satisfactory. All the animals on which operations of this class were performed recovered without accident.

I began afterward to study a technique which could possibly be used in the treatment of aneurysms

*Read at a meeting of the New York Academy of Medicine, February 17, 1910.

of the thoracic aorta. The ordinary methods for the suture and transplantation of vessels had to be modified. The aortic wall is very friable. It is easily cut by the threads, and hemorrhage or thrombosis occurs. Large silk threads must be used. On the ascending aorta, the wall of which is especially friable, I employed the stitches advocated by Jaboulay for arterial anastomoses. The ordinary technique of vascular sutures must be adapted to the anatomical conditions of the thoracic aorta in order to be safe. The aortic circulation cannot be interrupted for a long time without occurrence of nervous complications. When the descending aorta is clamped for more than ten or fifteen minutes, the posterior limbs become paralyzed. It seems that the clamping of the ascending aorta cannot be continued without danger for more than thirty seconds. It was, therefore, necessary to find out a method for diverting the blood during the long plastic operations. The diversion of the blood can be produced in two different ways—by temporary intubation of the aorta or by an artificial collateral circulation. It is a central or lateral diversion of the blood.

The central diversion consists of tubing the segment of the aorta which is to be resected. The vessel is laid open by a longitudinal incision and a paraffined tube is inserted into its lumen and temporarily fastened. This small operation involves only a short interruption of the circulation. Then the wall of the aorta can be extirpated and replaced while the circulation goes on through the tube. When the operation is completed, the tube is removed through a small incision of the wall of the aorta.

The lateral diversion consists in establishing a communication between the left ventricle and the descending aorta, or between two parts of the aorta. I have used only the first method. The anastomosis between the left ventricle and the descending aorta is made by means of a paraffined rubber tubing or of a large jugular vein preserved in cold storage. One end of the vessel or of the tube is inserted into the apex of the left ventricle and fastened. The other end is inserted into the descending aorta. The ascending aorta is clamped. Then the blood goes directly from the left ventricle to the descending aorta. The direction of the blood stream is reversed through the upper part of the descending aorta, which acts temporarily as an ascending aorta. There is, therefore, no danger of anemia of the brain. But the operation is still very dangerous because the details of the method are not sufficiently worked out. The mortality was heavy. Before being safe the technique must be considerably improved. Nevertheless, I succeeded twice in anastomosing the left ventricle to the descending aorta and in reversing the circulation through the upper part of the descending aorta, after clamping the arch of the aorta just above the heart.

In spite of the lack of accuracy of my technique, some of the animals which had undergone aortic operations remained in good health. The anatomical and clinical results could be observed after a few weeks or a few months. The sutures, anastomoses, and transplantation succeeded as well on the thoracic aorta as on the other vessels. A dog, the ascending aorta of which had been incised and sutured by Jaboulay stitches, died two months and a half after the operation. It was found that the wound had healed perfectly. The scar was very small. On three other dogs, the descending aorta had been severed transversely and united again by continuous through-and-through sutures. One of them was chloroformed two months and a half after the operation. The anastomosis was found normal, without dilatation or stenosis. The other dogs are still living in good health three months after the operation.

A small piece of the upper part of the descending aorta of a dog was resected and replaced by a piece of jugular vein preserved in cold storage. During the operation, which lasted twenty-four minutes, the blood reached the lower part of the aorta through a paraffined tube. The dog remained in good health. Twelve days after the operation, he died suddenly. The accident was due to a fault of technique in the preservation of the vein in cold storage.

Three months and twelve days ago, a segment about three centimeters long of jugular vein preserved in cold storage was transplanted on the descending aorta of a small dog. The animal is still in excellent health and there is no modification of the femoral pulse.

These results show that positive results can be obtained in plastic operations on the thoracic aorta. But, in order to be safer, the technique of the diversion of the blood must be improved.

I attempted afterward to find some methods which could be used in the treatment of certain diseases of the heart. This work is still in its beginning, and has given very little definitive results. Nevertheless, some of the operations were successful. Cardiotomy followed by suture with large silk thread does not present any danger. The opening of the heart and the introduction of the finger into its cavity does not interfere at all with the health of the aimal. The resection of a small part of the wall, followed by suture, is a little more dangerous, because the suture is made under tension. The threads may tear the wall.

I tried to develop an operation which could be used in certain cases of mitral insufficiency. It consists of producing a slight stenosis of the upper part of the left ventricle. It can be obtained by a partial cuneiform resection of the wall of the ventricle just below the coronary artery. A dog which has undergone this partial ventriculectomy a few weeks ago is still in good health.

In case of mitral stenosis, it would be easy to make an incision of the valve. But it could probably not produce a very good result. It would probably be better to establish an indirect auriculoventricular anastomosis by a vein implanted on the left auricle and ventricle. I am trying to develop the technique of this operation.

In certain cases of angina pectoris, when the mouth of the coronary arteries is calcified, it would be useful to establish a complementary circulation for the lower part of the artery. I attempted to perform an indirect anastomosis between the descending aorta and the left coronary artery. It was, for many reasons, a difficult operation. On account of the continuous motion of the heart, it was not easy to dissect and to suture the artery. In one case I implanted one end of a long carotid artery, preserved in cold storage, on the descending aorta. The other end was passed through the pericardium and anastomosed to the peripheral end of the coronary, near the pulmonary artery. Unfortunately, the operation was too slow. Three minutes after the interruption of the circulation, fibrillary contractions appeared, but the anastomosis took five minutes. By massage of the heart, the dog was kept alive. But he died less than two hours after-

wards. It shows that the anastomosis must be done in less than three minutes. Perhaps this can be obtained by using another technique, a tube of Payr, for instance.

These experiments must be considered only as a first step toward the plastic surgery of the heart and of the aorta. It is very probable that some diseases of these organs can be cured by surgical methods when an adequate technique will be found. But I am very far from saying that the operations I have described will be of practical value under their present form. I have performed only thirty-five operations on the thoracic organs. As these operations belong to many different classes, the technique of each one has not yet been sufficiently worked out. No complication followed the use of the method of Meltzer and Auer. Very extensive operations were rendered possible by the employment of their apparatus. It is certain that the method of Meltzer and Auer, by its simplicity and efficiency, is a great advance in the experimental surgery of the thoracic organs.

THE VALUE OF CONTINUOUS INTRATRACHEAL INSUFFLATION OF AIR (MELTZER) IN THORACIC SURGERY;

WITH DESCRIPTION OF AN APPARATUS.*

By CHARLES A. ELSBERG, M.D.,

NEW YORK.

ADJUNCT SURGEON, MT. SINAI HOSPITAL.

During the past year Meltzer and Auer have described a method of artificial respiration which they call "respiration by the continuous intratracheal insufflation of air"; they have shown that by this method, animals could be kept alive for many hours when one or both pleural cavities were widely open. A small tube was passed through the larynx into the trachea almost to the bifurcation, and by means of a foot bellows air mixed with ether was continuously blown into the tube under a pressure of 15 to 20 mm. of mercury. In the animals the lungs remained distended, and the excess of air passed upwards in the trachea and out through the larynx and mouth in a continuous stream. The animals remained alive and in good condition even when deeply under the effects of curare. Meltzer and Auer recommended this method as one that might prove to be of great value for operations within the thorax in man. Carrel and the writer then made use of the method for experimental intrathoracic surgery in animals. The writer had the good fortune to witness many of the experiments of Meltzer and Auer at the Rockefeller Institute for Medical Research. Through the kindness of Dr. Meltzer I was permitted to operate upon a large number of animals and to test the method for operative work in the thorax. A considerable number of operations was done on dogs which showed that the method was a very safe and simple one.

These experiments, in which I was assisted by Dr. H. Neuhof, will be published in detail later, but they led me to the conclusion that the method might be a very simple one for human surgery. In the following short paper I shall consider briefly the theoretical objections to and advantages of the method from the standpoint of its use in the human being, the practical aspects and the general technique of the method, and finally I shall describe an apparatus which I have devised for use in operations on man.

To be developed to a high extent, intrathoracic surgery must become the property of the many and not of the few. This will take place when a method has been discovered which will make it possible for any surgeon of experience to do operations within the thorax—as far as the anesthesia and the dangers from pneumothorax when the pleural cavity or cavities are opened are concerned—as safely as in other parts of the body. The apparatus must be a simple and inexpensive one so that it can be acquired by all. The negative pressure chamber of Sauerbruch and the positive pressure apparatus of Brauer and their modifications have been proven very satisfactory and of great practical value in intrathoracic operations upon man, but the apparatus is complicated and expensive, and therefore only few surgeons and hospitals possess such apparatus. The differential pressure chamber of Dr. Willy Meyer represents the most improved form of differential pressure cabinet, but the same objections must be made to it. The apparatus is cumbersome and expensive. It cannot be called simple. The apparatus required for Meltzer's method is certainly very simple, the method of operation is simple and easily learned. It has been shown to be very efficient for intrathoracic operations on animals. It remains to determine whether the method is as simple and safe for use on sick human beings.

From this standpoint, the following objections might be raised against the method: 1—That the introduction of a tube through the larynx into the trachea in human beings might be harmful, and its presence in the trachea for a period of time might be dangerous. 2—That the continuous current of air might injure the mucous membrane of the trachea or cause grave injury to the lungs. 3—That the distention of the lungs might be harmful, might cause interstitial emphysema, or predispose to pneumonia.

1. *What harm can be caused by the presence of a tube in the trachea?* It is well known that a long tracheotomy tube can be worn in the trachea for many months without danger. Anyone who has had any experience with bronchoscopy knows that a bronchoscopic tube can be kept in the trachea for considerable periods of time without danger to the patient. In the search for a small foreign body in a bronchus I have more than once had a rigid Killian tube in the trachea for 15 to 30 minutes without harm. The tube that is introduced in the method of Meltzer is of soft rubber which does not fill up the tracheal lumen nearly as much as the bronchoscopic tube. I believe we must avoid all theoretical prejudices and arrive at the conclusion that with the proper precautions the introduction and presence of a rubber tube in the trachea is free from danger.

2. *Will the continuous current of air be harmful?* The experiments of Meltzer and Auer, of Carrel, and of my own have shown that no injury was done to the dog's trachea in our experiments. From this it does not follow that the human trachea will be unharmed—especially the possible diseased trachea. I desire to call your special attention to the fact that in the animal experiments no care was taken to keep the air that was blown into the trachea either warm, sterile or moist. Notwithstanding the

*Read at the meeting of the N. Y. Academy of Medicine, February 17, 1910.

crudeness of the technique no apparent injury was done to the tracheal mucous membrane. If the method of insufflation was used in the human being, the air should be sterile, warm and moist, and in what follows I shall describe a very simple device by means of which all of this can be accomplished. The pressure of the air in the trachea should not be harmful. The pressure is equal to about 1-4 to 1-3 of a pound to the square inch, which is far within the danger zone. Dr. Meyer has stated in one of his publications, that workers in mines and in the foundations of bridges and high buildings often work for hours under a pressure of thirty or more pounds to the square inch.

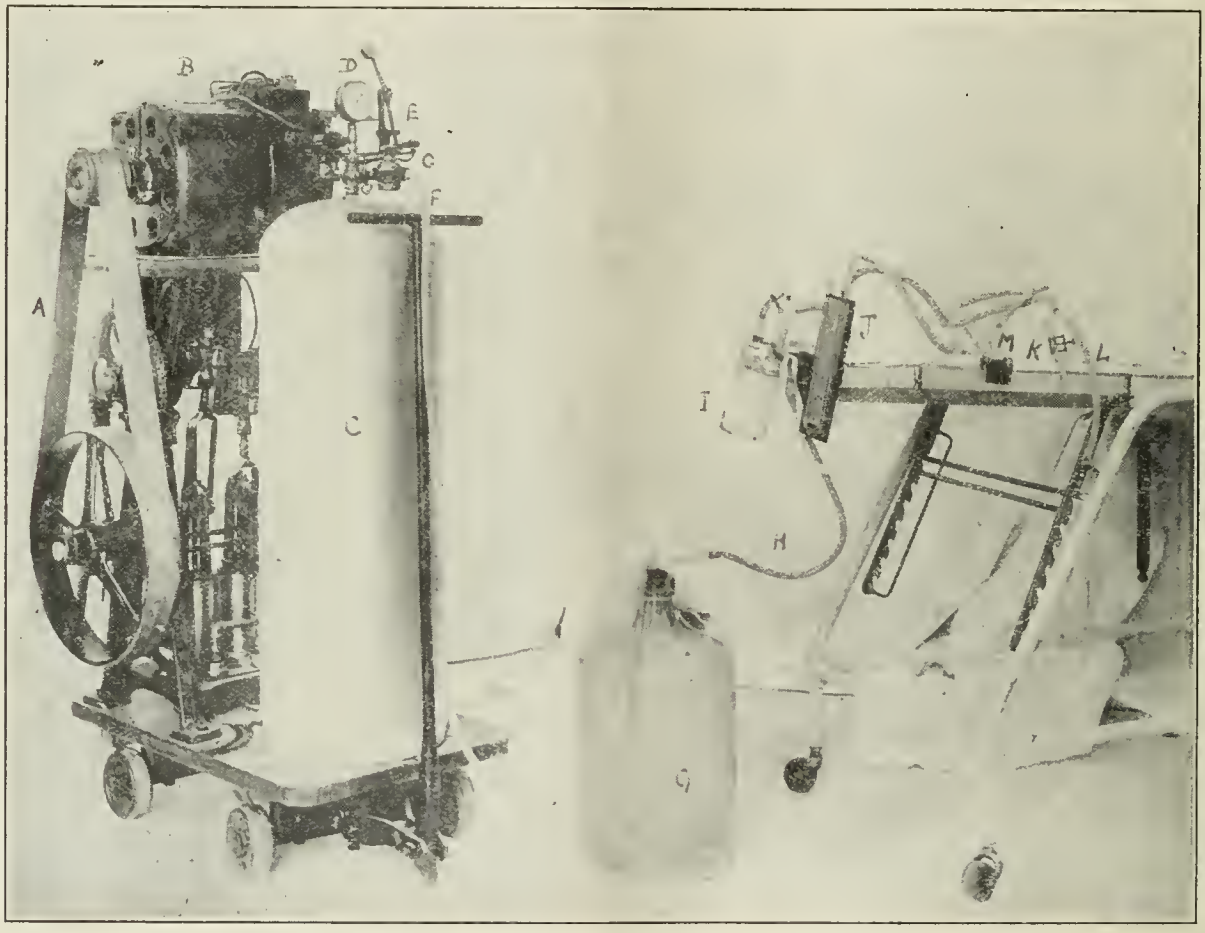
3. *Will the distention of the lungs be dangerous?* The degree of pressure will probably be safe for the reasons just stated. The pressure will probably not be much greater than that upon the lungs during expiration in a Brauer positive pressure apparatus. In animals, the continuous pressure has done no harm, but in man it will no doubt be advisable to collapse the lungs for a moment every five minutes or less. This can be accomplished by a simple manoeuvre. If the method was used in human surgery the current of air should be kept at a low pressure until the chest is open and then the pressure should be raised enough to moderately distend the lungs.

So far, the insufflation method has not yet been used in operations in the human being, but its very great efficiency in animal experiments would indicate that it might be equally valuable in man. It is only with much reserve that the results of experiments on healthy animals can be applied to sick human beings under our care, and every safeguard should be taken before a new method is tried on a human being. After careful study and much thought on the subject, I have laid out the following plan of procedure for the human being, and have devised an apparatus for the purpose:

The tube for introduction should be fairly rigid with an opening at its end like that in an ordinary rectal tube. It should contain an obturator which is to be removed as soon as the tube is in place. The obturator should be elastic and should have the proper laryngeal curve. This will make the introduction of the tube more easy and will prevent mucus from entering the tube while it is passed into the trachea. An appropriate laryngeal forceps should be on hand as it may be required. It may be advisable to anesthetize the larynx with cocain before the introduction. The patient is anesthetized and the mouth kept open by a mouth gag. One finger of the left hand is inserted into the mouth and the epiglottis pulled forward. The tube is then passed over the finger into the larynx and is pushed forward slowly until an obstruction is reached—which signifies that the end of the tube is at the bifurcation. The obturator is then withdrawn and the tube pulled out for about one inch. The tube is then threaded through a special gag made for the purpose, and the tube fixed to the gag. The tube is now ready to be attached to the air pump.

The gag which I have devised and which is being made for me, is held against the upper teeth by a head band, so that the lower jaw can be opened at will and the mouth cleaned out.

The insufflation apparatus which I have devised



Apparatus for the intratracheal insufflation of air in the human being. The apparatus is set up ready for use.

for hospital use is an automatic one.* It is mounted on a small truck so that it can be easily transported. A triple expansion pump (A) driven by an electric motor (B) delivers the air into the tank (C) which has a pressure gauge (D) and is connected with an automatic cut-off (E). The cut-off can be set for any pressure up to 60 pounds. A pressure regulator keeps the air which enters the tube (F) at a constant pressure. The air passes through the tube (F) into the bottle (G) which contains hot sterile water. The air bubbles through the water and is filtered, warmed and moistened. The tube (H) carries the warmed sterile air to the ether bottle (I) to which it is connected in such a manner that the air must either pass over the ether vapor and carry ether with it, or some of the air passes through the ether bottle, or all passes outside of the latter. By this means the air carried into the patient's trachea is either saturated with ether vapor, or contains only a small amount of ether or none at all. To one part of the tube (H) a tank of oxygen is connected so that the patient can be given oxygen in addition if desired. The tube from the ether bottle is connected to the manometer (J) by a side tube and has a Y ending. To one end of the Y endpiece is attached the safety vent (K) which is opened whenever the lungs are suddenly to be collapsed, and to the other end the tube (L) which is connected to the intratracheal tube.

A detailed description of the apparatus and its working will be published in the near future, but the following few statements will suffice for the understanding of its management. The motor is connected with the source of electricity and the tank filled with air. The stop cock (O) is then partially opened and the air allowed to bubble through the water bottle and finally to escape by the tube (L). The pinch screw on the tube (K) is then opened or closed until the manometer registers a pressure of 20 mm. The tube (L) is then united to the tube in the patient's trachea by means of a connecting tip. The apparatus is now working and the operation can be begun. By screwing down or unscrewing the pinch screw on tube (K) the pressure of air entering the trachea can be raised or lowered. Whenever the pressure gauge shows that the pressure in the tank has fallen to 10 the motor is started again and the tank refilled. The air in the tank has to be replenished every 15 to 20 minutes. The apparatus above described is larger and more bulky than required and I am having a much smaller apparatus constructed. An ordinary foot bellows can be used, but I believe that an automatically working apparatus is better for hospital use. I have had a wheel and handle attached to the pump so that the pump can be driven by hand if the current should give out or the motor be out of order. The entire apparatus will cost less than $100. If, however, a bellows be used as was used by Meltzer, and later by Carrel and by myself in our animal experiments, the entire apparatus should cost less than $25. It can be carried around in a hand bag.

I have great hopes that Meltzer's method of respiration by continuous intratracheal insufflation will be found of great value in operations on patients where the thoracic cavity has to be invaded. Much careful investigation is required before any positive statements can be made, but there is every justification for its trial on the human being. The positive and negative pressure chambers were recommended for human surgery because they had worked well in operations upon animals. With the insufflation method of Meltzer the thorax of dogs can be opened with impunity as far as the dangers from pneumothorax and sudden collapse of the lungs are concerned. If the method works as well in human beings as it does in animals, then we have at last a simple method by means of which the intrathoracic viscera will be brought within the domain of the surgeon.

The method may also be of great value in the treatment of asphyxia of all kinds—chloroform and ether asphyxia, opium poisoning, asphyxia neonatorum, coal gas poisoning, perhaps drowning, etc. We have resuscitated dogs after all respiration and heart action had ceased for several minutes by means of intratracheal insufflation. I have kept a patient with myasthenia gravis who had stopped breathing alive for five hours by means of intratracheal insufflation of air and oxygen. The patient was deeply asphyxiated when I was called to see her in the hospital ward, and her heart action could only be faintly heard. Without difficulty I passed a tube into her trachea through the larynx and began intratracheal insufflation. Within a few minutes the patient's color was pink and rosy and the heart action was re-established. For almost five hours the patient was kept alive with a good pulse, although she never once made a respiratory effort during that time. This is the first and up to the present time the only case in which the method has been used in the human being.*

*I desire, in this place, to express my acknowledgment and thanks to Dr. S. Yankauer of this city, whose help and suggestions were invaluable to me.

*Since the above was written, we have operated upon a patient with a pulmonary abscess, and have done the thoracotomy under the insufflation method. The operation was performed by Dr. Lilienthal at Mt. Sinai Hospital. From the standpoint of the method, the operation was very satisfactory. The anesthesia was easy and little ether was required; the patient's condition remained good during the entire operation; there was an entire absence of mucus in the trachea; the heart action was unchanged when the chest was opened; the lungs could be distended and collapsed at will; when the tube was removed after the pleura had been closed, the breathing was normal in character; recovery from the operation was prompt. The full details of this case will soon be published.

CURIOUS ARRANGEMENT OF THE CAPSULE OF THE LENS AFTER THE SIMPLE EXTRACTION OF CATARACT.

By DR. JUAN SANTOS FERNANDEZ,

HAVANA, CUBA.

THE discission of the capsule of the lens in cataract operation has been amply studied and has caused the invention of various instruments, from the commonly used needle of De Graefe to the forceps of Foester. All have the same object, that of rupturing or opening the anterior capsule or of tearing away a portion of it, in order to make certain of the delivery not only of the lens, but of the cortical masses that precede or follow it.

It has also been attempted to perform the discission with the point of the knife, at the time of making the keratotomy. Knapp, Gayet, and Galezowski were the first ones to adopt this method, although the first mentioned did not follow it long, for he now invariably uses the peripheral discission with the cystotome which at his hands gives most excellent results. In surgical practice habit holds

an important place as well as confidence. For the past fifteen years we have made the discission by means of the knife and have not repented so doing.

We do not pretend to say that the method is without disadvantages in some circumstances, but the same may be said of all methods. We believe that it should not be condemned, if for no other reason because with it we can operate with greater speed. Speed in an operation, the *cito* of the ancients, may not be an indispensable requirement, but should always be recommended. The body is thankful to the least possible amount of torture, or if not of torture at least of being touched or handled. Besides the discission with the point of the knife, while doing away with one of the steps of the operation, avoids one possible danger, the introduction of new instruments, which, with the least lack of care, may infect the interior of the eye or may produce some traumatism in a region so delicate.

We know very well that in nervous patients, in those with shallow anterior chamber, or where the level of the anterior surface of the lens is deeper, this procedure offers a slight difficulty, if one is not accustomed to direct the point of the knife towards the capsule; but generally it can be reached, and most of the time the rupture is larger than with the cystotome, so much so that we have never felt obliged to repeat the discission, as we have had to do sometimes when we used the ordinary cystotomes. We have at once made the tear of sufficient size to allow the delivery of the lens. The greatest obstacle we have met has been that sometimes, on account of the hardness of the capsule, the knife was not sufficiently slanted to enable its point to become disengaged, thus preventing its being passed through to perform the counter puncture. However, by drawing the knife slightly backwards or placing it sidewise, the difficulty ceases and the corneal section can be finished.

The fact we allude to, although observed in one of our patients, was in one not operated upon by us, but by a notable foreign colleague. He consulted us some time after having been operated upon. He informed us that he noticed some reduction of the visual field, although his acuteness of vision was perfect after his aphakia had been properly corrected.

Our patient was a man of 46 years, with a myopia of 7 d. spherical, and a slight posterior staphyloma. At the operation a simple extraction of the right eye had been performed. De Graefe's knife had been used to perform the capsulotomy. After the pupil was dilated we examined him and saw in the middle of the anterior capsule an orifice that was the cause of the lessened visual field.

We recommended our patient to wait until the other eye was operated upon, because even if the same thing should occur in this eye, the reduction of the visual field would be insignificant, as he would then be in possession of binocular vision. Before he could be operated upon the patient died. We have mentioned this case to demonstrate how rare this accident is, as in nearly 20 years that we have been practising the discission almost exclusively with the knife, we have not observed it in one of our patients. Besides, the slight reduction of the visual field is not a serious inconvenience, considering that the patient had perfect vision and the prospect of improving, had the other eye been operated upon.

LUMBAR ANALGESIA.

By MAX BREUER, M.D.,

BUFFALO, N. Y.

GYNECOLOGIST TO THE GERMAN HOSPITAL; CONSULTING GYNECOLOGIST TO THE GERMAN DEACONESS HOSPITAL.

The demonstrations of the Bucharest surgeon, Jonnesco, in New York and elsewhere will undoubtedly revive the interest in lumbar analgesia, with which procedure American surgeons are not as familiar as they might be. When I read a paper in the Buffalo Academy of Medicine four years ago on this subject, there was no discussion to speak of, not from lack of interest, I am sure, but because nobody present had any experience in the matter. At that time I reported my first cases of lumbar analgesia. My further experience with this method of operating, which at my suggestion has been taken up by Dr. Mansperger at he German Deaconess Hospital, entitles me to say that lumbar analgesia, which is a popular method in France and Germany—some European surgeons have reported 800 and 1,000 cases and the number of cases on record is over 50,000 to-day—has come to stay. I do not think, however, I may be too conservative, that lumbar analgesia should or ever will replace general anesthesia, but if for some good reason general anesthesia is contraindicated or if it is dreaded by the patient, the lumbar analgesia, as worked out in Bier's clinic, is a very useful, and, in the hands of a competent man, a safe procedure. A line drawn across the umbilicus gives the limit of the field of operation which it is safe to anesthetize, although one is able by exaggerated Trendelenburg position to reach higher nerve roots from the lumbar subarachnoidal puncture. The demonstrations of Jonnesco and his publication in the *Deutsche medizinische Wochenschrift*, December 9, have not convinced me that it is really safe to go further, unless one is willing to take risks for good reasons. Bier and Rehn have declared Jonnesco's advanced method as dangerous.

The lumbar analgesia is particularly indicated in patients suffering from cachexia phthisis, Bright's disease, heart lesions, senile changes, etc., and is life saving, I believe, if one has to do a major operation during shock after accidents. The procedure is contraindicated in septic cases and advanced arteriosclerosis. The analgesia lasts, in my experience, from 50 to 70 minutes and is complete, if the technique is correct. Only the best material should be used and stovaine in 0.04 doses is a reliable drug, as I have found out in my cases. Bier uses of late, as I saw in Berlin this summer, tropococaine. One ampule contains 1.3 cm. of a 5 per cent. tropacocaine solution with the addition of 0.00013 suprarenin. The point of puncture is between the first and second, or between the second and third lumbar vertebræ. Absolute asepsis is of course indispensable. The selected area is painted with tincture of iodine. The patient sits on the operating table sideways, his feet resting on a chair, and has to bring his spinal column into an extreme curve. An assistant pressing his flat hand against the stomach will help him to accomplish that. Ethyl chloride spray, or, if you prefer, a small dose of morphine subcutaneously will add to the patient's ease. After straightening out as much as possible all lateral deviations of the spinal column, the needle is put through the skin only, as closely as possible to the lower vertebræ. The patient usually straightens up

at this moment. After he has resumed the right position, and after you have convinced yourself, looking from above downward, that the needle is in the median line, the stylet is removed, and the needle, pushed forward and slightly upward, will enter the canal 3 to 5 mm. wide, between the two halves of the cauda equina. The proof of the proper puncture of the subarachnoidal space is the appearance of the cerebrospinal fluid in a stream, not in drops. In case of failure retract the needle and bring it forward again, trying to reach the median line. After injecting the drug, aspirate some liquor and inject again, otherwise you will lose the drug remaining in the needle. In the canal mentioned the drug can circulate freely and reach the nerves of the cauda and the roots of the branching off nerves. As the nerves in the cauda are strictly separated in sensory and motor nerves, the posteriorly located sensory nerves are the ones to be reached and, therefore, the point of the needle should stop immediately when the liquor flows. The technique is not quite easy in cases of spinal deformity. By deviating with the point of the needle, one is apt to inject the drug between the nerves of the cauda, which produces an unsatisfactory, usually semilateral, analgesia and that may be exactly the side not desired. If an abdominal operation—appendectomy, herniotomy, adnex operation—is conetmplated, a moderate Trendelenburg position is indicated; in operations lower down the horizontal position is preferable. The results in my hand have been delightful; after-effects, headache or backache were hardly noticed. I believe nobody, who has seen a prostatectomy performed in lumbar analgesia will want to do this operation again under general anesthesia. The patient does not need to miss a meal and has a far better chance for recovery. Mackenrodt of Berlin, one of the boldest and most skillful gynecologists, reports the lowering of the death rate in his radical operations for advanced cases of carcinoma uteri with removal of pelvic glands by 9 per cent., since he adopted lumbar analgesia. The most advanced cases of carcinoma uteri are as a rule sent to him. He has not seen any undesirable after effects from his last 200 cases of lumbar analgesia, but he does not think that stovaine is as safe as tropacocaine. Bier himself has declared himself in favor of tropacocaine. In my own observation I failed to see any disturbance of respiration, the pulse usually fell off in numbers, not much in quality.

One man, operated upon for abscess of the vesicula seminales, asked for his dinner when being taken from the operating room. A paralysis of the abducens, which disappeared fully after three weeks, developed in that case only. In pus cases I would refuse to use lumbar analgesia, not on the strength of this one case, but from the study of the literature. If the proper technique is applied, the right instrument and the right drug, there ought to be no failures.

Ectopic Pregnancy.—Hunter Robb says that death from ruptured ectopic pregnancy is the result of shock rather than hemorrhage. He advises against immediate operation if the patient is in a state of shock.—*The Ohio State Medical Journal.*

Specific Diseases Transmitted from Animals to Man.—The most frequent of these are tuberculosis (?), pleuropneumonia (?), anthrax, septicemia, glanders, trichinosis, foot and mouth disease of cattle, tenia or tapeworm, and actinomycosis. These diseases belong to the department of pathology, and are in no sense chemical.—Bartley in *The Long Island Medical Journal.*

Shock in Early Life.—Pisek says that the young organism with its unstable nervous organism and low resisting powers is particularly susceptible to shock. The younger the individual the greater is this susceptibility. In the newborn the blood, too, is still in a transitional form and the supporting powers of this vital fluid are easily undermined.—*The Post-Graduate.*

The Different Aspects of Infantile Surgery According to Age.—Kirmesson remarks on the two great groups of surgical affections that are frequent in childhood and infancy, the affections of the locomotor apparatus and the congenital deformities, such as hare-lip, spina bifida, club-foot, and imperforate anus. Many forms of suppuration are also frequent in infants, such as suppurations of the umbilicus, erysipelas, and skin affections. Among children under five years of age dislocations are rare, while after that age we see them of the hip and wrist. In infants we get fracture of the femoral diaphysis from slight causes, and fractures of the leg and arm are rare. In early infancy the epiphysis is elastic and cartilagenous, and yields to violence; in childhood and adolescence are seen most of the traumatisms of the epiphysis. Invagination of the intestine is peculiar to infants, appendicitis occurs only later in childhood. Hernia is strangulated only in later childhood, most obstructions in babies being spasmodic and relieved by chloroform. Over five years osteomyelitis involves the tibia; under it the lower end of the femur. Tuberculosis in infants involves a single point; later it may be multiple or general. So we see that each age has its favorite diseases and locations for pathological lesions and accidents.—*Le Bulletin Médical.*

Contagion of Tuberculosis by Dry Dust.—P. Le Noir and Jean Camus have made interesting experiments to ascertain the infective value of bacilli contained in dry dust of sputum. The opinion derived from researches made by various authors has led to very great difference of opinion on this subject, some thinking that only wet sputum was dangerous, others that the breathing of particles of dry dust from rooms where tuberculous patients have lived was equally dangerous. The authors took a single tuberculous ward in the Hospital St. Antoine as the place of experiment, and here they placed three colonies of guinea-pigs in different locations. One entirely unprotected was placed on the floor; another, protected by wire netting, so that it could not be touched by the patient, was also placed on the floor; a third was placed just under the ceiling, and was fed from a ladder. Of the entire number of animals used in the experiment, ten in all, four were infected, the lesions being abdominal. The authors believe that the danger from tuberculosis of dried dust in the air is indisputable. The hospital conditions of tuberculous patients are very imperfect, and although there is little danger in the contact for a few minutes or hours with these patients, to live with them is not without danger. They are also a source of danger of reinfection to one another. The danger is still greater in the homes of the poor, where hygienic measures are wanting, than in a properly conducted hospital.—*La Presse Médicale.*

Cuneiform Lacunæ, or Erosions Called "Chemical" of the Teeth, a Manifestation of Abortive Mercurial Stomatitis.—G. Milan describes certain erosions, or ivory ulcerations occurring in syphilitic patients under the influence of mercurial injections. While the mercurial treatment is going on, the patient becomes sensible of pain on breathing cold air, drinking cold or hot liquids or similar actions, which increases with the treatment and stops when the mercury is no longer used. Examination shows that there are grooves on the teeth from side to side, in which the ivory is absent, the sensitive portion of the tooth being exposed along the edge of the gums. The bottom of the cavity is white, shining, hard, and polished; it is triangular in shape and different in appearance from caries. The front teeth are more frequently involved than the others, and the labial surface than the other faces. The persons attacked by this lesion are adults from 20 to 50 years of age, and in good health. Various theories have been evolved to account for this lesion; that of chemical action and of too severe brushing of the teeth are given. The author describes a case which conclusively shows that the condition occurs under the influence of mercury and ceases when its administration is stopped. The author believes that it occurs in persons who use good hygiene, and takes the place of the ordinary stomatitis of dirty people. Preventive treatment consists in frequent brushing, and careful administration of mercury, stopping when tenderness of the teeth appears.—*Le Progrès Médical.*

MEDICAL RECORD.

A SAFE AND SANE FOURTH OF JULY.

IT appears somewhat early in the year to discuss the Fourth of July, but, coming events cast their shadows before and therefore it may be as well to take time by the forelock. True it is that a vast quantity of ink has been spilled in reprobating the doings of past Fourths and perhaps little or no attention will be paid to lucubrations on the subject either in this or other journals. The most hopeful symptom of the situation is that in all parts of the country individuals are beginning to recognize that the manner in which the freedom of America is celebrated demonstrates the fact that a proportion of the inhabitants are not capable of using their freedom in a sensible way. The medical as well as the lay press has oft and with emphasis deprecated the action of those ill-advised persons who make day and part of the night hideous by the noisy and foul smelling pyrotechnical apparatus which they discharge on the public streets. American cities are noisy enough in their everyday routine, and the pandemonium which takes place in the beginning of July must be a culminating point in the nervous strain to which many of its neurasthenic citizens are subjected. The wise and those who are able flee the cities of America on the most auspicious date in the history of the country as from a pestilence. Although the strictures which have been passed in medical and lay journals concerning the riot of noise and the bloodshed which occur annually may not seem to have borne fruit, yet it is likely that these appeals to common sense have carried some weight, at least with the more sober inhabitants.

A perusal of an article which appears in the *Forum* for March of this year, written by Mrs. Isaac L. Rice, lends strength to this view. Mrs. Rice points out that the Society for the Suppression of Unnecessary Noise through its president has corresponded with men of eminence in all lines of life whose patriotism cannot be questioned and who have responded with surprising unanimity in favor of observing a safe and sane Fourth. Mrs. Rice is of the opinion that a most potent factor in this direction has been the set of tables of Independence Day casualties prepared by the *Journal of the American Medical Association*. As a striking object lesson on the menace to life and limb of the Fourth are placed side by side with the casualty list the deaths and injuries which resulted from seven famous Revolutionary battles. The following is the table:

Battles.	Killed and Wounded.	Celebration.	Killed and Wounded.
Lexington	83	July 4, 1903	4,449
Bunker Hill	449	July 4, 1904	4,169
Fort Moultrie	37	July 4, 1905	5,176
White Plains	100	July 4, 1906	5,466
Fort Washington	149	July 4, 1907	4,413
Monmouth	229	July 4, 1908	5,623
Cowpens	72	July 4, 1909	5,307
	1,119		34,603

A pungent commentary, indeed, on the advancement of civilization in this favored New World is this table, a careful study of which we would recommend to the Mayor of New York City, who is reported to be disposed to let the children and hoodlums have their fling on this great day. According to newspaper report, he has rescinded the order of the Fire Commissioner prohibiting the sale of explosives around the Fourth, and has consequently assumed responsibility for all the deaths and maiming, as well as for the destruction of property resulting directly and indirectly from this noisy and murderous celebration.

GOLF AS A FACTOR IN THE PUBLIC HEALTH OF A COMMUNITY.

THAT the playing of golf is a factor of considerable importance as regards public health is an argument which affords no scope for discussion. Perhaps it will be allowed on all hands that the game from every conceivable standpoint is healthy. It is suited to persons of all ages. The young find in it a sufficiently strenuous game, bringing into action possibly as many muscles as any sport, with the exception of rowing. For the middle-aged man or woman it is an ideal game, seeing that it does not necessarily make too great a call upon the physical powers, while it is preeminently of all outdoor diversions the one which requires the greatest skill—in fact, trains the mental faculties quite as much as it does the physical. For the old, again, it is almost the only open-air game which can be played with zest and at the same time in a leisurely manner; and, lastly, it acts as an incentive to exercise when otherwise exercise might not be taken. For professional men it is the only game. How did such men living in New York, London, or other large cities spend their hours of leisure before golf came into vogue? Indeed, what did many of them do with their long vacations? Answers to these questions are not easy to give. Maybe they went for a walk in the afternoon in fine weather, perhaps during the longer vacations they went abroad or into the country and fished or hunted. But there is a very large number of men who care not for fishing or hunting. The professional man of the city, the physician, for instance, not infrequently, unless he be one of those fortunate or unfortunate men who are always busy, has hours of leisure in which he absolutely is at a loss how best to occupy his time. A wise man admits to himself—and, better still, acts on the admission—that he needs healthy relaxation at intervals. The strain and stress of city work, and especially of such work as falls to the lot of the physician, is long continued, too much so for the ordinary individual. Furthermore, it is not rational to labor in this fashion. The man who does so in the long run

breaks down, or even if he keeps going does not accomplish work equal to that of the man who indulges in play occasionally. In the neighborhood of every large city there are golf courses, which are as a rule easily reached. Thus the overworked physician has the opportunity, whenever he can spare the leisure, for playing a game which combines fresh air, good exercise, mental training, and congenial society. It has been aptly said of golf that it is the game which tries weak humanity the most, it lays the soul bare and reveals a man's true nature. Accordingly, it is an excellent school of discipline—another point in its favor.

For Americans in particular golf is, or at any rate should be, an untold boon. In a general way the American after the age of twenty-five or earlier gives up games entirely. He regards them as childish and sets himself to the stern business of amassing riches and in doing this often, more often than not, loses his health. He is likely to become dyspeptic, irritable, and a creature of nerves. He will work unceasingly for ten months of the year and then for a holiday will rush to Europe with his womankind and be dragged about sightseeing, almost as arduous toil as the practice of his profession or business. Golf affords him the chance of getting wholesome exercise in the fresh air at least once in the week, and there are few who have tried it but will say that they are better physically and mentally for the invigorating change from the dull routine of work. Much might be said also of the immense benefit that golf has exerted on the women of America. It is quite as well adapted to women as to men and is by far the best game for the so-called weaker sex which has ever been introduced. The more energetic games, as lawn tennis, are not at all times to be recommended for all women; but it is seldom that golf has any effect but a good one. It goes without saying that a game which tends to render a woman constitutionally and physically stronger is for the good of the race at large.

Professional and business men of this country, although golf has made amazing strides, do not participate in the game to the extent that their British brethren do. This statement applies with more truth to physicians than to members of other professions. In London and in the great cities, physicians from the highest to the lowest, from Harley street to Whitechapel, play golf whenever they can get away, and who shall deny that thereby they show wisdom? In any event there is no doubt that golf is a great and increasing factor of the public health of a community.

MAN AND THE FLY AS TYPHOID CARRIERS.

With a better understanding of the very considerable proportion of apparently healthy persons in every community who are persistent or occasional harborers and disseminators of the typhoid bacillus, comes a clearer appreciation of the highly dangerous qualities of human excreta. While sufficient work has not as yet been done to give us exact information as to the percentage of such "carriers" in the general population of this country, still the findings of the board which has been investigating typhoid fever in Washington, D. C.—that three in one thousand healthy persons with no history of previous typhoid were found to be such "carriers"—are highly illuminative. This proportion for the city of Washington is probably not far from correct for the country at large, especially since it closely approximates the ratio found to exist in Germany in the same classes of persons. The German investigators, moreover, found that among healthy persons who gave a clear history of having had typhoid fever, two per cent. were "carriers" of the typhoid germs.

With any such proportion in the general population of healthy human beings serving as reservoirs of typhoid germs, as indicated in the investigations above mentioned, the general prevalence of typhoid fever in our military camps in the Spanish War is no longer difficult to understand. It will be remembered that not a single regiment in all our armed forces escaped unscathed, and that it seemed frequently absolutely impossible to trace the infection back to any antecedent case. We can now understand that probably every new regiment contained on recruitment a half dozen or more unsuspected harborers of the typhoid germs, whose excreta soon specifically infected all the latrines throughout the camps.

Inasmuch as at the present time there is no ready method for the detection of these typhoid carriers, a logical deduction from our knowledge of their common existence is that all aggregations of human excreta, as found in the privy pits of country resorts or in the latrines of camps, must hereafter be considered from a broader sanitary standpoint and regarded as not only undeniably offensive but as most probably infectious. With such an efficient system of sewage disposal as is possessed by most cities, the matter of the infectivity of human dejecta is not of as much sanitary significance, but under less prompt and complete conditions of removal it assumes great importance. The general necessity for the destruction, removal, or disinfection of masses of human excreta, whether known to contain the discharges from sufferers with typhoid fever or not, must therefore be accepted as a fundamental sanitary requirement. And this is especially the case during the warmer months when the pestiferous fly is active in serving not only as an intermediate vehicle but as a host of typhoid germs. Now comes an English army surgeon who reports experiments made by him upon flies reared artificially from eggs laid in human fecal matter infected with typhoid. These flies, after emerging from the pupal state, were promptly removed from the infectious material in which they were hatched and upon which they had fed as larvæ, and were subsequently fed on clean food under clean conditions. Several of these flies were killed daily, their bodies thoroughly flamed to destroy germs on their surfaces, and their intestines teased out, macerated, and nutrient media inoculated therefrom. In nearly every case these cultures developed typhoid growth, the last remaining fly giving it on the sixteenth day after removal from the typhoid material. Clearly, flies, like human hosts, may long preserve these germs in their intestinal tracts—and their mode of

development and filthy habits of feeding make them much more liable to acquire such dangerous infection, while the elimination of the latter in the dejecta as "fly-specks" enables it to remain unnoticed where human excreta would be readily apparent through sight and smell. Nor do we know as yet the full period of time through which typhoid infection may persist in the fly intestine. Undoubtedly it is longer than the sixteen-day period already determined, and it is perhaps not too much to assume that infected flies, after hibernating during the winter, may perhaps emerge in the spring already capable of transmitting the infection hidden away within their bodies. It is also certain that where masses of excreta are exposed to flies their destruction or disinfection should occur at no longer intervals than the seven to ten-day period which elapses from the deposition of the egg to the emergence of the adult insect. When such masses suffer belated disinfection, the broods of flies which have already hatched out in their filth and are suffered to escape are probably perpetuating the infection and able to scatter it broadcast through new fields of activity.

From the above we can draw many lessons and morals. Among them, we may admit that the Biblical quotation, "A man's foes are they of his own household" has a special applicability to the typhoid question. Another that the fly, whose character as a disease carrier constantly becomes blacker on closer investigation, is one of the worst enemies with which the human race has to contend.

Metallic Sounds in Intestinal Obstruction.

Though auscultation of the thorax is probably the most commonly used of all diagnostic methods, auscultation of the abdomen is a part of physical examination the value of which is not so generally appreciated. In certain cases, however, the recognition of various sounds in the abdomen, either arising spontaneously or produced by the aid of percussion, is of distinct value and often a great aid in the diagnosis of disease. In determining the size of an organ, especially of the stomach, there is probably no method, excepting the *x*-ray, which gives results of as uniform accuracy as does the simple procedure of auscultatory percussion. The systolic bruit and snapping sounds accompanying aneurysm are of prime importance in diagnosing disease of the abdominal aorta. There are, too, various intrinsic sounds in the intestines, which if properly appreciated are of some importance. The common borborygmi or gurgling sounds occur where there is meteorism accompanied by active peristalsis, and are especially pronounced in the later stages of intestinal obstruction. In the *Münchener medizinische Wochenschrift* for February 1, 1910, Wilms describes some peculiar metallic sounds produced in the bowel which he believes to be of high diagnostic value. He has noticed that when a loop of the colon, and especially of the cecum or the sigmoid is distended to a certain tension, and the abdominal wall over it is percussed, a peculiar high-pitched metallic ring is produced, which is easily distinguished by means of the stethoscope. Studying further into the question of this metallic sound he discovered that it may also be produced spontaneously when the bowel is distended, contains a certain proportion of fluid and gas, and is in active peristalsis, this sound being produced by the shock of the gas bubbles striking against the tense gut wall. The conditions requisite for the appearance of the phenomenon are met with in the early stage of intestinal obstruction, and Wilms considers that, in the absence of postoperative meteorism, their presence indicates an immediate exploratory laparotomy. He has made use of the phenomenon in a considerable series of abdominal conditions, and claims that it is thoroughly reliable as a pathognomonic sign of intestinal obstruction.

Posture in the Recognition of Tricuspid Disease.

The diagnosis of involvement of the tricuspid valve is often far from simple, especially in cases of mild disease or relative incompetency, in which the murmur appears only under certain stress. In such cases change of posture or exercise may bring out a murmur previously unheard, and such procedures are carried out by every careful diagnostician who suspects a lesion of this valve. In the *Archives of Diagnosis* for January, 1910, Heinrich Stern describes a posture which he says has not previously been described and of great aid in diagnosing the condition. To quote Stern's own words, he has "found that it is often possible to induce the murmurs which are characteristic of tricuspid disease when they have been absent, and to accentuate them so that they are better audible and distinguishable in case they be present, but are vague and indistinct. We generally examine the heart while the individual is in the erect or recumbent position, and the more painstaking of us examine our patients by utilizing both postures. When a patient is on his back and there is any tendency to distention of the jugular veins, it will be evinced there and then. By lowering the head of the patient, while he is still on his back, the jugular veins become more distended, as a rule, and may begin to pulsate. Distention of the vein, or its pulsation, will increase in direct ratio to the lowering of the head, but when a certain point is reached, which is dependent upon individual factors, the pulsation diminishes more or less and the engorgement may also recede. This lowering of the head, which in reality is but an extension, a stretching of the muscles of the neck, the veins, etc., is reflected in the tricuspid area, where now murmurs are noticed that were not perceptible before or which had been quite indistinct." As the posture produces an increase of the tricuspid incompetency, and may induce dyspnea, cyanosis, and pulsation of the liver, it is important that it be maintained only so long as is absolutely necessary. For this reason the examiner "must be ready to proceed with the examination, stethoscope attached to the ears, at the very moment the patient has assumed the posture. He should stand behind the patient, somewhat to the right of the head of the latter when an examining table is utilized. In case the examination is made in bed, the physician should be sitting at the right side of the head of the patient, who has been placed across the bed. In both cases the head of the patient should be supported by either the left hand of the examiner, or in advanced cases by both hands of an attendant. It should not be dropped at once over the edge of the examining table or bed, but should be brought down very gradually and be immediately elevated as soon as the dyspnea and the venous engorgement become excessive."

News of the Week.

A New Theory of Beriberi.—At the meeting of the Far Eastern Tropical Medical Association in Manila last week, Dr. Henry Fraser, director of the Straits Settlements Institute of Medical Research, offered the theory that beriberi is due to a lack of phosphorus in the food. The steam milling rice process, he said, is at fault, because the high polish which produces the best quality of white rice removes the phosphorus contained in the pericarp. He had found that the use of the cheaper grades of unpolished rice, or the mixing of white rice with the polishings, restores the phosphorus and eliminates beriberi. Dr. Aron of the Philippine Medical School, who had been working independently of Dr. Fraser and experimenting on animals and natives, announced that he had reached the same conclusion.

Endowment of the Chair of Medicine in the University and Bellevue Hospital Medical College.—Announcement is made that Mrs. Helen Hartley Jenkins had given $100,000 for the endowment of the Chair of Medicine in the University and Bellevue Hospital Medical College. The gift is made through Dr. A. Alexander Smith, and in recognition of the long friendship existing between the donor and Dr. Smith, and of the interest of the donor's father, Marcellus Hartley, in New York University. Mr. Hartley was a member of the university corporation from 1895 until his death and a member of the Committee on the Medical College from the time of the consolidation of the two medical schools. The foundation will be named the Marcellus Hartley Chair of Medicine.

The College of Physicians and Surgeons.—Closer relations are being established between the medical department of Columbia University and the Mt. Sinai and German Hospitals in New York. The following members of the staffs of the hospitals have received appointments in Columbia University. From Mt. Sinai Hospital Drs. Brill, Libman, Gerster, and Berg, and from the German Hospital, Drs. Kammerer, Stadtmüller, and Hensel.

Cornell University has decided to change the curriculum of its medical department so that but one year will be spent at Ithaca and three in New York instead of two years in each city as is done at present.

New York Polyclinic Medical School.—At a recent meeting of the faculty of the New York Polyclinic Medical School and Hospital, Dr. M. D. Lederman was elected Clinical Professor of Laryngology and Rhinology.

The Forsyth Dental Infirmary is soon to be incorporated in Boston as a result of a donation of $2,000,000 made by Mr. Thomas A. Forsyth of that city. The infirmary is to be located in Hemenway street in the Back Bay, is to be thoroughly equipped and manned for modern dental surgery, and is to be free to any child under sixteen years of age. The purpose of the clinic is to give free care of the teeth to every child in Boston.

The New York State Board of Health is planning a systematic campaign against communicable diseases. The plan is to divide the entire State into districts, in each of which will be appointed a competent physician to act as sanitary supervisor under authority of the State Board of Health.

Charitable Bequests.—By the will of the late Mary A. Duffy of Philadelphia the sum of $200 is bequeathed to the Little Sisters of the Poor and to the Free Hospital for Consumptives. By the will of the late Henry C. Fox of Philadelphia the sum of $5,000 is bequeathed to each of the following institutions: Masonic Home of Pennsylvania, Presbyterian Hospital, Howard Hospital and Infirmary for Incurables, and the German Hospital.

Sanitary Conditions in Paris.—The prophecy of widespread disease in Paris which was made at the time of the recent floods appears not to have been fulfilled. The vital statistics of the city show that its health is better than at this time last year.

The Third International Congress of School Hygienics will be held in Paris August 2 to 7, 1910, under the honorary presidency of the Minister of Public Instruction. Applications for all information concerning: The reports and notices should be made to the General Secretary, Dr. Dufestel, 10, Boulevard Magenta, Paris; concerning the exhibition, to Mr. V.-H. Freidel, Musée Pédagogique, 41, Rue Gay-Lussac, Paris; and concerning the conditions for the voyages, lodgings, and excursions to the Agence Lubin, 36, Boulevard Haussmann, Paris.

Physician Pardoned.—Governor Carroll of Iowa, upon recommendation of the State Board of Parole, has pardoned Dr. J. W. Crofford of Decatur county, who in 1905 was sent to the penitentiary for twelve years for the murder of a patient in his hospital at Lamoni. Newly discovered evidence showing that the man is innocent formed the grounds for the pardon.

The Association of American Medical Colleges will hold its twentieth annual meeting at Baltimore, Md., March 21-22, 1910, in the Hall of the Medico-Chirurgical Faculty, of Maryland. The president of the association is Dr. George H. Hoxie of the University of Kansas, and the secretary-treasurer is Dr. Fred. C. Zapffe of the University of Illinois.

The British Medical Association will hold its seventy-eighth annual meeting in London, July 26 to July 29, 1910. The president's address will be delivered on Tuesday, July 26 and the sections will meet on the three following days. The annual representative meeting will be held on Friday, July 22, 1910. The address on medicine will be delivered by John Mitchell Bruce, M. D., F. R. C. P., of London, and the address in surgery by Harry Gilbert Barling, B. S., F. R. C. S., of Birmingham. The president of the association is Sir William Whitla and the president-elect Mr. H. T. Butlin.

The Providence (R. I.) Medical Society, at the annual meeting held March 2, elected the following officers: *President,* Dr. J. C. Rutherford; *Vice-President,* F. P. Capron; *Secretary,* Frank Mears Adams; *Treasurer,* Winthrop A. Risk; *Counsellor,* Dr. J. H. Akers.

The Jackson County (Mo.) Medical Society has elected Dr. H. E. Pearse *president* in the place of Dr. B. Clark Hyde, who was elected in December but resigned. The other officers are: *Vice-president,* Dr. J. D. Griffith; *Treasurer,* Dr. W. F. Kuhn; *Secretary,* Dr. E. L. Stewart.

The Nye County (Nev.) Medical Society was formed at a meeting held in Tonopah recently. The following officers were elected: *President,* Dr. Sydney Clark; *Vice-president,* Dr. J. R. Cunningham; *Secretary* and *Treasurer,* Dr. C. J. Richards; *Board of Censors,* Drs. W. W. Ashley, R. J. Mapes, and E. S. Grigsby.

The Trumbull County (Ohio) Medical Society at a meeting held at Newark March 2, 1910, elected the following officers: *President,* Dr. D. G. Simpson; *Vice-president,* Dr. H. A. Sherwood; *Secretary* and *Treasurer,* Dr. F. K. Smith; *Censor,* Dr. T. M. Sabin.

County Medical Societies Unite.—At a meeting of the St. Joseph-Buchanan County Medical Society, held recently at St. Joseph, a proposition to consolidate the society with the Andrew County Medical Society was approved, and resolutions to that effect were drafted. The combined organization will meet monthly in St. Joseph, excepting once or twice a year, when meetings will be held at Savannah.

Dr. Frederic Prosch, a French medical missionary in East Africa, died suddenly of fever on February 28. Dr. Prosch had done missionary work in Africa for ten years, during which time his health had been gradually undermined by the debilitating climate, and his collapse was attributed to a weakened condition that could not resist an attack that he might have survived a few years ago. On the day previous to his sudden death he was apparently in good health, having taken luncheon with ex-President Roosevelt.

Obituary Notes.—Dr. John A. Beauchamp of Nashville, Tenn., died suddenly on February 27, 1910, of heart disease, aged 70 years. He was a graduate of the Medical Department of the University of Nashville in 1861. Dr. Beauchamp had been for nearly fifty years on the staff of the Central Hospital for the Insane, having been superintendent of the institution since 1894. He was a member of the Davidson County Medical Society, the Tennessee State Medical Society, and the American Medical Association.

Dr. Mary E. McCarty of St. Louis, Mo., died at her home on March 3, 1910. She was a graduate of the Homeopathic Medical College of Missouri in 1890.

Dr. Frank V. Cantwell of Trenton, N. J., died at his home March 11, 1910, aged 47 years. He was a graduate of the University of Pennsylvania in 1884, and was surgeon to St. Francis Hospital. Dr. Cantwell was a member of the Mercer County Medical Society, the Medical Society of New Jersey and the American Medical Association.

Dr. Richard M. Pancoast of Philadelphia died on March 4, 1910, at the age of 85 years. He was graduated from Jefferson Medical College in the class of 1845.

Dr. Samuel Smith Brecht of Manheim, Pa., died on March 3 at the age of 79 years. He was graduated from Pennsylvania Medical College in the class of 1859.

Dr. Harrison T. Witman of Reading, Pa., died on March 6 at the age of 72 years. He was graduated from Jefferson Medical College in the class of 1864. He served during the Civil War as surgeon in the 195th Pennsylvania Regiment.

Dr. Daniel B. D. Deaver of Wernersville, Pa., died at Okahumpka, Fla., on March 6, at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1861.

Dr. Benjamin J. Throckmorton of McKinney, Texas, died in Dallas February 24, 1910, aged 54 years. He was the son of a former governor of Texas, and was a graduate of the Louisville Medical College in 1888.

Dr. Mandeville Thum of Louisville, Ky., died on March 4, 1910, aged 42 years. He was a graduate of the Kentucky School of Medicine.

Dr. Mathias Cook of Utica, N. Y., died at his home March 7, 1910. He was a graduate of the Starling Medical College in 1864 and served as surgeon in the Civil War and also in the Franco-Prussian War.

Dr. William Diehl of Brooklyn died at his home March 11, 1910, aged 46 years. He was a graduate of the New York Homeopathic Medical College in 1891.

Dr. Louis E. Magnenat of Amarillo, Tex., died at his home February 25, 1910, aged 41 years. He was a graduate of the University of Texas in 1895, and a member of the Potter County Medical Society, the State Medical Association of Texas, and the American Medical Association. He was once on the teaching staff of the University of Texas.

Dr. Frank R. Porter of New Winsor, Col., died at the Loveland Hospital on March 4, 1910. He was a graduate of the New York University Medical College in 1882.

Dr. Thomas C. Stockton of San Diego, Cal., died on March 2, 1910, aged 72 years. He was a graduate of the Bellevue Hospital Medical College in 1868 and was the pioneer physician of San Diego.

Dr. H. E. Baine of Waco, Tex., died at his home March 1, 1910, aged 56 years. He was a graduate of the Hospital College of Medicine in Louisville, Ky., in 1875.

Dr. James Levi Day of St. Louis, Mo., died March 1, 1910, aged 69 years. He was a graduate of Washington University in 1873 and a veteran of the Civil War.

Dr. George E. Ehle of Grand Rapids, Mich., died in the University of Michigan Hospital recently, aged 62 years. He was a graduate of the Hahnemann Medical College in Chicago in 1882.

Dr. R. E. Graham of Columbia, Mo., dropped dead in his office March 3, 1910, aged 40 years. He was a graduate of the University of Missouri in 1894.

Correspondence.

CALLING A SPADE A SPADE.

To the Editor of the Medical Record:

Sir:—It is most refreshing to learn from the March 5 issue of the *Survey* that out in the glorious climate of the Pacific Coast a society has been organized to deal with matters venereal, which boldly calls itself the California Association for the Study and Prevention of Syphilis and Gonorrhea. The association is composed of forty members, one-half of whom are physicians; and a woman, Dr. Frances M. Greene, has been chosen as president. The avowed purposes are to treat venereal diseases as frankly infectious; to habituate the public to hear and speak of them without embarrassment, and thus to drag them into the light, where all men may know and avoid them.

The first public meeting was held in January, and an audience of several hundred men and women listened to addresses by Dr. David Starr Jordan of Stanford University and other prominent men. In conjunction with the assembly was an exhibit, prepared by the Secretary of the State Board of Health. It is interesting to note that no account of the affair appeared in the daily papers, although several reporters were present. One local paper, however, published an account of the meeting.

But a campaign of publicity and education is bound to succeed. There is every reason why venereal diseases should be dealt with in a candid and straightforward manner. All mystery and a world of humbuggery would be swept away by open discussion and timely instruction. Some day, perhaps, young men will know that chastity is compatible with perfect health, and "what every woman knows" will include a knowledge of the significance of venereal disease.

Addison W. Baird, M.D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

POOR LAW REFORM AND MEDICAL RELIEF—HUNTERIAN LECTURES ON NEGRO RACES—MIDDLE-EAR DISEASE—PREVENTION OF MALARIA—HOSPITALS—CANCER CHARITY—A QUACK'S APPEAL DISMISSED—OBITUARY.

LONDON, February 25, 1910.

ALL the week questions connected with the Poor Law, including, of course, medical relief under its administration, have been prominent. At the Guildhall the Central Poor Law Conference was welcomed by the Lord Mayor, and its discussions, extending over two days, have exhibited most divergent opinions on nearly all points. The two reports of the Royal Commission had each their supporters among the speakers, and each was as freely condemned by others who had equal experience. A resolution was carried by a large majority to the effect that while approving of reasonable reforms in the present system the conference emphatically condemned the revolutionary proposals forming part of the minority report. A further resolution was carried referring to a committee the recommendations from both reports, with a view of sending to the boards of guardians those which they may conclude should be adopted by the country.

On the second day the conference spent the morning in a long general discussion, which ended without any resolution being adopted. In the afternoon session an address on the "Reform of Poor Law Medical Relief" was delivered by Dr. C. T. Parsons, of the Fulham Infirmary. He advocated the encouragement of the sick poor to seek medical aid at the earliest moment, application to be made direct to the doctor, the necessary inquiry as to the case being proper for help at the public expense to be considered afterwards. All drugs and appliances, he maintained, ought to be provided by the public authority—not, as is too often the case in small districts, at the expense of the doctor, who naturally could not adopt very costly methods of treatment, the result being in some cases that patients were not restored to work and continued a charge on the rates. In the next place, Dr. Parsons insisted on an increase of the emoluments of the service in order to make it more attractive to medical men. He would encourage them to specialize, though in this, perhaps, he would hardly be supported by his brethren, and it certainly seems doubtful whether specialists should take charge either of large districts or infirmaries on the one hand or of smaller ones on the other. Good all-round men would find plenty to do and full opportunity of improvement. Then Dr. Parsons advocated the co-ordination of the Poor Law, Asylum, and Sanitary Services under one body—say a committee of the County Council. There would then grow up in each county a large public medical service, which, if properly staffed, paid, and graded, with promotion according to merit, would attract ambitious men to enter it. The inadequacy of payment at present existing resulted in many evils. An underpaid service of any kind was sure to be inefficient, and in the end expensive, too. Men should be encouraged to do their best work for the service.

Several speakers thought Dr. Parsons had been too severe on the system. Dr. Toogood found the condition of the sick in London far better now than when he entered the service a quarter of a century ago. The nursing to-day was as good as in the general hospitals. A hearty vote of thanks was accorded to Dr. Parsons at the conclusion of the conference.

Dr. John McVail of Glasgow, who was medical investigator to the Royal Commission on the Poor Law, has delivered a lecture on the medical treatment of the poor, advocating the establishment all over the country of medical provident institutions assisted by the State, each managed by a committee representative of the members, the doctors, and the State. The interests of the great friendly societies must be considered and in some cases they could be associated. A merely voluntary system would be incomplete, but compulsion would be difficult. If compulsion could not be insisted on, the State must offer direct and indirect inducements. Dr. McVail did not see why paupers should not obtain medical aid through the provident institutions. The local authority could act through them. Whatever might be done to provide a substitute for the Poor Law would be necessary to avoid anything which would deter or degrade the really deserving unfortunate; the vicious, the idler, and the loafer must be controlled, but apart from the institutions he advocated.

During the week Prof. Keith has delivered the two remaining lectures of his Hunterian course on the characteristics and relationships of the negro races. Their broad and short faces and prominent cheek bones, he said, depended on the robust development of the teeth and muscles of mastication. Their prominent jaws were ascribed partly but not entirely to the size of the teeth. The protuberant jaws gave not only large mouth and palate, but ample passage for air through nose and throat. The small jaws of Europeans were due to an arrest of normal growth providing a place for the permanent teeth. This contracted the pharynx—hence adenoids. The European condition seemed connected with civilization, but how was not known. There was some evidence that the growth of the jaws was regulated by some internal secretion, but not to suggest disuse. The width of the negro's cheek was only apparent; on an average it was less than the European's; the appearance was due to narrowness of the head behind the ears—a characteristic of children, too. The flatness of the negro's nose was also only apparent, due to the cheeks projecting so far beneath the eyes. The European cheeks had receded and left the nose prominent.

As to the brain, the lecturer said our knowledge is too imperfect for an analysis of its features in the negro. It was smaller than the European's, but so many factors influence weight that measurements must not be given too much importance. The outline of the brain chambers of the negro skull was totally different from that of apes and of the Neanderthal race. The final test of the brain's quality was the degree of success with which it could preserve its owner. When black civilization met European competition it might go hard with the darker race. An instructive incident occurred as the lecturer was preparing illustrations for these lectures. He took two brains at random, one a negro's, the other a British sailor's. When slides were made he found that in number and complexity of convolutions the brain of the black was the larger and the more elaborate. But this would not be the case if a number of brains were compared.

With regard to relationship to other races, the manner in which the pygmy tribes were scattered in the Congo was referred to. In South Africa the pygmy negroes were represented by the bushmen—a race which must, said the lecturer, be assigned to the negro race from their physical characters. The bushman stood to the Hottentot as did the Congo pygmy to the true negro. The pygmy was found also outside Africa, but only as mere isolated meshes of a human net spread over the southern half of the Old World at one time. Curiously the distribution of the small negro was coextensive with the larger bodied race. Wherever the large negro is found isolated pygmy tribes are sure to crop up. Kollmann held that the pigmy was the primitive form of man, but the lecturer thought this view was negatived by all available evidence. As to the evolution of the negro, the lecturer regarded the extinct Tasmanians as probably the earliest. Still, this Tasmanian was, from a zoological point of view, a very highly evolved man. The native Australian, though deeply pigmented, was probably a good representative of the stock from which the white man arose. The paleolithic man of Europe resembled the native Australian more than any known race. In Tasmania and Australia fifty years ago there could have been seen side by side comparatively early stages of the division of the primitive human race into negroes and non-negroes. It is a striking fact that in every large area where primitive races are found in the southern half of the Old World neighboring representatives of the Tasmanian and Australian stocks are also to be found.

Middle ear disease was the subject of some practical talk at the Harveian Society last Friday. It arose in a paper by Mr. Gay French, who dealt with the etiology, bacteriology, and complications. As to treatment, he strongly protested against the use of the syringe as well as the insufflation of powders, and advocated free drainage and antiseptic drops. He dwelt on the importance of examining and treating the nasal, nasopharyngeal, and oral cavities. His favorite plan, where possible, is to pass hot air loaded with antiseptics through the Eustachian tube into the middle ear. He showed the apparatus he used for this purpose. The tempera-

ture of the air he recommended was 140° F., the application being made daily for about five minutes at a time. He said that out of eight cases treated for a fortnight in this way he could speak of five cures, and the other three were benefited. He spoke well of fibrolysin in some cases of tinnitus. Dr. William Hill said he thought the author had been too severe on the syringe and he could not see how hot air could act.

Dr. Fitzgerald Powell defended the syringe, which, properly and carefully used, is safe enough. Of course, it may be abused, as may other things. Drs. Stuart Low and Andrew Wylie both condemned syringing. The latter used hot air for deafness, but not for suppuration. Dr. Atkinson enlarged small openings in the membrane and used suction. Dr. Dan Mackenzie had not been fortunate with hot air and remarked that labyrinthine disease was more frequent than commonly supposed and might perhaps be due sometimes to careless syringing.

There was quite a considerable assembly on Tuesday at the Chamber of Commerce when Dr. W. J. Simpson gave a lecture on the prevention of malaria. He told his audience that the discovery of the cause and mode of spreading of the disease had made it much less difficult for sanitarians to devise methods of stamping out the disease. When drainage, reclamation, and so on had done their work, the new methods would enable the residents in the tropics to defend themselves. Their aim must be to exterminate the mosquito within the precincts of their village or town. Its life was particularly open to attack in its larval stage, when it breeds in water. A systematic plan had been successful at Ismailia, the Malay States, etc. The Americans had changed the pestilential locality of Panama into a more healthy district than various places in the United States. Dr. Simpson urged that "no mosquitos, no malaria" should be placarded in every school, church, and public building in malarious countries. The children should be taught to recognize the larvæ and destroy them. If boy and girl scouts in every village hunted for and reported where the larval enemy was found the locality would soon be cleared. No one should go to a malarious country without a mosquito curtain and full instruction how to use it and its importance.

The annual report of King's College Hospital, presented yesterday, referred to the separation of the college and hospital as regrettable but likely to prove of benefit to both. The new hospital would be approaching completion in between two and three years. There was a deficit on the year's working.

Yesterday also was held the annual meeting of the Middlesex Hospital. Here again a deficit was reported—a too frequent occurrence in hospitals. The cancer charity in connection with this hospital does not directly benefit it. The £250,000 received from the Barnato trustees cannot be used for the general benefit of the hospital, but the income from it must be spent in maintaining the new cancer wards. During the year 157 in-patients have been treated for cancer.

Yesterday the Court of Appeal dismissed the application of the man who traded on the public as "hypnotist, bloodless surgeon, and medical and electrical specialist." A jury had awarded £1,000 damages to a man who had given him that amount to teach the business and be his head assistant. Against this verdict he had the temerity to appeal. The Master of the Rolls, in giving the judgment of the court for dismissal, spoke of his having declared he had American and other diplomas and was a duly qualified doctor, and said "a more gross lie could not be imagined. He had no qualification in this country nor in the United States." He had had to confess he had never been across the Atlantic. "There was ample evidence that he was an ignorant, unscrupulous quack, and was not carrying on an honest business." Appeal dismissed.

The death is announced to-day of Dr. Le Rossignol, who was a magistrate of the Royal Court of Jersey and consulting surgeon to the hospital. He was in his sixty-eighth year and had held many important posts in the island. He was a graduate of Aberdeen, 1868, and had taken the science degree in France. He had been president of the Jersey Medical Society.

Dr. Samuel Evans died at Dovercourt on the 6th inst., aged 63. He had been Mayor of Harwich, Admiralty Surgeon, Medical Officer to the Trinity House, and held other appointments.

Dr. Spencer Hughes, late of Bromley, died on the 12th inst., aged 82. He qualified in 1855-1856 and had retired for several years.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

MENINGITIS—THE CAMPAIGN AGAINST TUBERCULOSIS—INTESTINAL PARASITES.

MANILA, P. I., January 31, 1910.

A STUDY of the statistics of the Bureau of Health for the past few years shows that an unusually large number of deaths from meningitis were reported among children; for instance, for the three months ended December 31, 1905, there were 80 cases; 1906, 81 cases; 1907, 151; 1908, 129. During the early part of the same quarter for 1909 it was decided to make autopsies in such cases; the first few showed that the deaths were in reality due to cholera. As soon as it became known that all cases of meningitis were to be autopsied, the number reported dropped and only 29 were diagnosed for the whole quarter, but even these, upon autopsy, proved to be 12 cases of cholera, 8 of beriberi, and 9 of meningitis. The foregoing experience provides additional evidence of the manner in which it is possible for cholera to be tided over from one outbreak to another and shows the necessity of continuing research work with regard to the epidemiology of this disease.

The campaign against tuberculosis in the Philippine Islands is now commencing to take much more definite shape. A large tract of land at San Juan del Monte, which is an elevated site just on the outskirts of the city of Manila, has been secured for the purpose of establishing a station which is to be used principally as a night camp. The intention is to admit persons afflicted with tuberculosis in the incipent stage, who are engaged in earning their living during the day, to go to the camp to sleep at night, where they may be taught the advantages of outdoor sleeping, the manner of disposing of their sputum, and the value of plain, simple food. It is the intention to give lectures at the camp from time to time in the native dialects which will deal with the hygiene of tuberculosis. The public will also be invited. After several months of instruction of this kind it is the intention to send these persons back to their homes and to admit a new set of patients. The former patients will be visited in their homes by nurses, in order to ascertain whether they are carrying out the things which they had been taught at the camp.

An out-patient tuberculosis dispensary has already been established for some months under the auspices of the Philippine General Hospital. The medical service to this clinic is furnished by the staff of the Philippine Medical School. It is now the intention to enlarge this tuberculosis dispensary by combining with the forces of the Bureau of Health, thus bringing many more resources to its disposal. Persons who desire to be admitted to the night camp will first have to be reported upon by the doctors connected with the out-patient dispensary. A nursing service will be added for the purpose of aiding in the clinic and making domiciliary visits.

Since the completion of the first work of examining the residents of the Philippines for intestinal parasites on a large scale, which was carried out under the direction of the Bureau of Health at Bilibid Prison, considerable additional work has been done and some idea of their prevalence in the residents of the Island of Luzon may now be had. Of the more than 3,000 prisoners examined at Bilibad, 84 per cent. were found infected with intestinal parasites. Of these, 60 per cent., or 52 per cent. of the total number of prisoners, had hookworms, 50 per cent. had whipworms, 23 per cent. amebæ, and 21 per cent. harbored some other species of parasite.

The commission which was put into the field at Tay Tay under the joint auspices of the Bureau of Science, the Philippine Medical School, and the Bureau of Health, examined approximately 1,000 persons and found 95 per cent. of them harbored one or more kinds of intestinal parasites and 10 per cent. had hookworms.

Later the Bureau of Health placed a commission in the field at Las Piñas, which is a town located on Manila Bay, almost equidistant between Manila and Cavite, and the site consists almost entirely of sandy soil in contradistinction to Tay Tay, which has a clay soil. The work at Las Piñas was finished September 30, 1909, with the following results: Six thousand were examined; of this number 24.2 per cent. of the males and 8.06 per cent. of the females were found to

be infected with hookworm, or an average of 16.13 per cent. of the population were found to be hosts of this health-destroying parasite. About 90 per cent. of the entire population were found to be infected with some form of intestinal worms and frequently with two or more kinds.

In order that data from an entirely different section might become available, the commission was transferred to Tuguegarao, Cagayan, which is an inland town in Northern Luzon, almost 100 kilometers from the mouth of the Cagayan River. The results up to December 31, 1909, have been as follows: Examined, 1,685; of this number 12 per cent. of the males and 7.1 per cent. of the females were found to be infected with hookworms, or an average of 9.55 per cent. of those examined were found to be infected; 74.37 per cent. were found to harbor some form of intestinal parasites and frequently with two or more kinds.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 3, 1910.

The Rehabilitation of Neurasthenia.—According to Philip Coombs Knapp there has been in recent years a tendency to minimize the frequency of neurasthenia and to emphasize the psychical element in the cases which were once classed under this heading. He says that there are obsessed patients where obsession is in a measure primary who are not neurasthenic. They are often the victims of some congenital or inherited psychopathic disposition; their affliction is often indicative of a considerable mental abnormality, and the outlook for recovery is often more grave than that of the neurasthenic. There are also many neurasthenics who become so from psychical causes and sometimes as the result of their obsessions and phobias. It is too soon, however, to speed the passing of neurasthenia and to call it all ideo-obsessive. There is a true nervous exhaustion, predominantly cerebral, characterized by irritable weakness and ready exhaustibility and when obsessions exist they develop secondarily as a result of neurasthenia. Too much emphasis has been laid on the psychical element in neurasthenic conditions: there is a real nervous exhaustion which demands the best therapeutic efforts on the physical side. These cases should be more deeply analyzed to determine how much is due to physical and how much to morbid psychical processes and whether the psychical disturbance is the cause or the result of the neurasthenia.

The Aftermath of Childbirth.—W. P. Manton shows the reasons why in spite of enlarged experience, exacter methods of observation and improved technique there has not been a decrease in those accidents of parturition which he groups under the term "aftermath of childbirth." He does not advocate the primary suturing of a lacerated cervix but thinks it better to wait until the parts appear more normal and proper instruments and competent help can be secured which is often impossible in general practice at the time that the tear occurs. He is firmly convinced that the less the practitioner has to do with the upper parturient passages immediately following childbirth the larger will be his percentage of good recoveries. There should be intervention only when a vessel is severed. The mere skin suturing of a lacerated perineum is not sufficient; the lower vaginal tissues must be included in the repair work. The repair of the ruptured tissues must be undertaken as soon after labor as possible. Mere inspection of the parts following delivery is not sufficient, a careful digital examination should be made with the forefinger in the rectum and the thumb in the vagina so that the thickness of each lateral sulcus and the supraperineal space should be exactly gauged and the amount and kind of mischief accurately determined. In cases of lacerations higher up from overstretching or the stripping of the vaginal mucosa from the subjacent tissue the repair should be effected at once. The edges of the vaginal wound should be brought together by catgut, while the external skin is closed by silkworm gut, certain sutures of which must be carried far enough upward to include the interlevator tissue.

New York Medical Journal, March 5, 1910.

A Case of Multiple Exostoses Coupled with Syringomyelia.—Clarence P. Oberndorf believes that multiple exostoses is a condition sufficiently rare to be considered worthy of reporting, especially when coupled with another rather infrequent condition, syringomyelia, at the age of eighteen, and with acromegalic symptoms. Among the interesting features in this case were (1) the spontaneous disappearance of the growths; (2) the absence of hereditary influence or rachitis; (3) the absence of any infectious agency; (4) the nervous symptoms which caused the following reflections: A. Were the exostoses the result of a latent morbid derangement in the gray matter of the spinal cord? B. Or were the syringomyelic symptoms due to pressure of an exostosis causing a dilatation of the central canal of the cord? The idea of attributing the exostoses to incipient cord disease, or possibly pituitary glandular secretory disorder, lacks substantial foundation. It is more reasonable to attribute the symptoms to tumors growing within the spinal canal, causing bilateral pressure. This pressure in turn produced the dilatation of the central canal below, involving the posterior horns of the cord and causing syringomyelia. In regard to the multiple exostoses one may generalize as follows: (1) While heredity is striking in some instances, it does not always exist as a factor and when occurring does not throw any light on the real pathogenesis of the disease. (2) The rachitic and tuberculous theories seem insufficient and unsatisfactory. (3) The coexistence of syringomyelia and multiple exostoses recalls and may lead to Charcot's theory that the centers for the regulation of osseous nutrition lie in the gray substance of the cord. (4) That cord pressure symptoms, considering the great number of exostoses in all cases, are exceptionally rare. (5) That even when the location of the growth pressing on the cord can be established, operation is hardly indicated, at least not before maturity, because of possible retrogression of the tumor, the possible future occurrence of existence of tumors at other points in the canal, and the fact that results to date hardly justify surgical interference.

School Dentistry Hysteria.—The object of this paper by S. W. Newmayer is to consider the various phases of dental conditions found in school children, the methods of examination as now practised, the reasons for not obtaining practical results, and the seeming impossibility of the work. The object of this paper is not to belittle the ill effects due to decayed teeth; he expects to see in time new school buildings being erected with arrangements for a clinic room properly outfitted, in which room a physician, trained nurse, and dentist will be in constant attendance. The examination of the mouths of school children would show that 90 to 95 per cent. were in need of attention. All school children should be taught a few simple rules on the care of the mouth and teeth, such as "Use a tooth brush properly daily or more often. Use a simple antiseptic alkaline mouth wash frequently, especially after meals and at bedtime. This need not be one of the expensive advertised mouth washes as plain lime water is as effective. Don't misuse the teeth by biting nuts and other hard substances. Don't pick the teeth with a pen-knife or any sharp instrument. Go to a dentist at least once a year whether you have pain or not." Teach the child early and there will soon be a marked improvement in the condition of the mouth, less carious teeth, and better health.

Recurrent Dislocation of the Patella.—Sinclair Tousey reports such a case which was complicated with chronic hydrarthrosis cured by high frequency currents. The indications for treatment were to cause absorption of the serous effusion in the joint and a return of the serous membrane to a normal condition, and to restore tone to the relaxed ligaments which permitted subluxation. The sole treatment adopted was the application of high frequency currents from glass vacuum electrodes exhausted to a vacuum of 0.001 atmosphere and giving a shower of tiny, almost invisible, sparks when rubbed over the surface. Eight treatments were given, and the knees became stronger after the treatment was stopped.

The Effective Treatment of Pompholyx.—George Edward Barnes says the first purpose of treatment is to free the skin of foreign bodies by passing with sufficient pressure the back of a knife over the diseased surfaces until every vesicle is burst. Then wash with sterile water and soap. A weak solution of lead, zinc, or bichloride of mercury may or may not be applied. The parts should be protected with a dry sterile dressing. As new vesicles appear they should be treated in the same way. When the thick, shiny, parchmentlike skin appears, it can be softened and stimulated by the use of oleum cadini in some simple vehicle.

Journal of the American Medical Association, March 5, 1910.

Blood Cultures in Typhoid Fever.—J. C. Topp remarks on the advance in technic which has enabled us to prove that typhoid bacteremia is constant in the disease by the bile culture media method introduced by Conradi, Kayser, and others, and says that it offers an almost certain means of diagnosis in the early stage of the disease, though progressively less helpful in the later stages. The

findings of the bacillus in blood cultures and the Widal agglutination reaction are in a certain sense complementary to each other, the former becoming less reliable as the disease progresses and the reliability of the latter increasing. The combination of the clot culture with the Widal test greatly enhances the value of the latter. Another advantage of the culture is its definiteness, and still another is in distinguishing typhoid from paratyphoid. In the latter, cultures are as valuable as in true typhoid, the paratyphoid bacillus being distinguished from the typhoid chiefly by its action on certain sugars. Todd gives the technique, with special cautions as to certain points, preferring the drawing of blood from a vein when possible, though the simple ear puncture will be sufficient when the other is not feasible. The medium used by the majority of workers is simple ox-bile or pig-bile sterilized in an autoclave. He uses a 12 or 15 per cent. solution of Squibb's inspissated ox-gall and sometimes adds 1 to 2 per cent. of peptone. When a Gram-negative motile bacillus is found, it may be reported at once as very probably the typhoid bacillus, but further tests should be used, such as gas formation in dextrose media and indol production. The time required for the detection of the bacillus is usually twenty-four hours.

Chronic Arthritis.—E. H. Ochsner discusses the diagnosis and treatment of arthritis deformans or chronic arthritis as distinguished from septic, tuberculous, gonorrheal, and syphilitic arthritis, gout, flatfoot, and chronic articular rheumatism. The principal source of confusion in the diagnosis, he says, seems to arise from the fact that even prominent authors and clinicians fail to differentiate between that form of chronic arthritis which develops subsequent to acute articular rheumatism and true arthritis deformans. He cannot agree with Strümpell that it is impossible to differentiate between the two. He believes that arthritis deformans is a disease as distinct from chronic rheumatism as is syphilis from tuberculosis, and as easily distinguished from it. This is important, as the two types of arthritis call for entirely different treatment. True chronic articular rheumatism is always secondary to acute articular rheumatism, while arthritis deformans, on the other hand, is insidious in its onset and chronic from the beginning and may not reach its development for several years, while it may be limited primarily to one joint, it gradually extends to the others and different joints may be in different stages of the disease at the same time. In chronic articular rheumatism we find the results of an acute and subacute inflammation of the synovial membrane which is lacking in arthritis deformans where the process seems largely confined to the joint cartilages and extraarticular structures. Patients with chronic articular rheumatism are greatly benefited by hot baths, sweats, and Bier's active hyperemia, while arthritis deformans patients are made worse by these measures. The differences in the history of development, the characteristic deformity, and the therapeutic test make a differential diagnosis possible in practically every case. Ochsner sees no evidence of a microbic origin of arthritis deformans, and as little for a nervous origin. The remedies recommended have been numerous, and he thinks that this affords a presumption that none of them is of any special value. To Ochsner, a case of arthritis deformans presents the following picture: We have, he says, to begin with, some factor which causes articular and pariarticular irritation. This in turn causes more or less constant pain, which results in non-nutrition and loss of resistance. If the process is not checked this soon results in a vicious circle, one factor causing the next until the patient finally becomes so exhausted as to be a bedridden cripple and an easy prey to an intercurrent affection. He regards it as a chemical rather than as an infectious process which takes place in the disorder. The first thing in treatment is prophlaxis, and he believes that many cases are aborted by the removal of offending appendices, hemorroids, and other causes of irritation. The treatment that he believes to be most effective in advanced cases is in relieving the pain, which, in its turn, will improve the nutrition, and this, in his opinion, is best secured by absolute immobilization. During his work on tuberculous joints he has discovered that relief of pain in an inflamed joint involved the recognition of two separate and distinct principles: First, an absolutely rigid, close-fitting retention dressing. Second, the application of this dressing with the limb in such a position that the antagonistic muscles surrounding the joint are in absolute equilibrium. If this can be secured by absolute immobilization, pain in any chronically inflamed joint will cease. If contractures are very pronounced and the limb cannot be brought into the desired position without extreme pain, the contractures are broken up and, if necessary, the tendons lengthened by plastic operation, and the limb is placed in plaster-of-Paris dressing in the proper position and allowed to remain there until the pain and irritation have fully subsided. Details of the method for different joints are given. He reports two cases and says that, in concluding, he would like to emphasize the following points: "First, that a clear differentiation is absolutely necessary to the successful treatment of these chronic joint affections; second, that beginning cases of arthritis deformans should be carefully studied, the cause ascertained and removed whenever this is possible; third, that, for the present, at least, it is well to be rather cautious in the treatment of the intermediary cases; and, finally, that even in the very late and apparently hopeless cases the patients can usually be greatly benefited by proper treatment." While the results are not to be considered always a perfect cure, Oschner has had considerable success in bettering the condition, and has several patients who have been bedridden for years now making their own living.

Rabies.—L. Frothingham reviews the history of rabies and the researches which have been made, especially the advances made in our knowledge by the work of Pasteur and his coworkers. The discovery by Negri, in 1903, of the bodies which go under his name brings us probably very close to the origin of the disease and enables us to recognize it without the trouble of inoculation. The effects of proper laws for muzzling dogs in various European countries are mentioned. The statistics of rabies in the State of Massachusetts are given, showing a great increase during the last two years, and Frothingham considers these figures far too low to represent the actual state of affairs. Many other States would show a similar or worse record, he thinks, if figures were obtainable, but they are difficult to secure. He answers the objections of those who deny the existence of rabies and oppose the Pasteur treatment, and shows how the latter has been successful as a prophylactic. After the disease has developed there is no cure, but with prior Pasteur inoculations all but a fraction of 1 per cent. can be saved. The utility of animal experimentation is amply demonstrated by the success of the Pasteur method. The misleading statements of Caroline E. White are noticed. Some of them are absolutely incorrect, like the statement that there are no Pasteur institutes in Germany. Others are misleading inferences wilfully drawn from facts that are directly opposed to the views she advocates. The fact that there is no hydrophobia to speak of in England and no Pasteur institutes is due to the rigid requirement for licensing and muzzling dogs. Their relaxation in 1892 was immediately followed by the reappearance of the disease, and fifty-one persons died in the next five years from hydrophobia. At present muzzles are not required in England, but will be resumed with the appearance of the first case of rabies. Moreover, there is a strict quarantine of six months imposed on any dog brought into the country. It is true to only a certain extent that similar results cannot be produced in this country. We could greatly reduce the disease, if not absolutely abolish it. Even local measures for muzzling will be of value if properly enforced, and an inadequate muzzling sometimes does good by preventing a dog from spreading the disease. If those opposed to animal experimentation, and to Pasteur institutes in particular, would devote their energies to the bringing about of the enactment and enforcement of muzzling laws, they could do great good in eradicating hydrophobia without any more annoyance to their animal friends than we regularly inflict on our draught animals in harness.

Bacillus-Carriers.—Alice Hamilton says we are greatly in need of some method for the detection of bacillus-carriers which is quicker and less cumbersome than the bacteriological examination of the stools and urine. Aside from the difficulties of these, and the time lost in making them, there is the other disadvantage of intermittency in the excretion of typhoid and paratyphoid bacilli which makes it possible for the carrier to escape detection. The agglutination test is positive in a certain proportion of cases, but in the opsonic index we have apparently a means of diagnosis more rapid than the bacteriological method and more constant than agglutination. Recently the writer undertook a search for typhoid bacillus-carriers among twenty-four patients with a history of gall-bladder disease, using the agglutination and opsonic tests simultaneously with the bacteriological examinations. Seven of these had a decidedly abnormal index to typhoid and paratyphoid bacilli, and repeated examinations showed that this was constant. Those suffering from acute symptoms had a fluctuating index, low and high, while in the others it was always high, never falling to normal; five of the seven agglutinated typhoid or paratyphoid bacilli or both in dilutions of 1 to 50 or more. The bacteriological examinations

showed that all seven were bacillus-carriers, five of paratyphoid, two of typhoid. Of the seventeen non-carriers none agglutinated either variety of bacilli in dilutions as high as 1 to 50, and none had a decidedly or persistently abnormal index. As the opsonic index was abnormal in 100 per cent. and the agglutination test positive in only 71 per cent., the former is clearly the most valuable. The test can be made rapidly and easily, and in the case of an unexplained epidemic in a hospital, the work could be simplified by first taking the opsonic test of the suspects and supplementing it with the bacteriologic one where the index was abnormal. In making these tests, the serum of both the suspected person and the control should be heated to 58° Centigrade for fifteen or twenty minutes. This destroys the lysin for typhoid bacilli while the heat-resisting element in the opsonin remains, making a decided contrast between normal serum, which contains but very little of this element, and immune serum, which is usually very rich in it.

The Lancet, February 26, 1910.

Pericardial Effusion: Its Diagnosis and Treatment.—Samuel West calls attention to the physical signs of pericardial effusion. Among the earliest are an increase in dullness outward and upward on the left side along the third left space or rib and the disappearance of the cardiohepatic notch on the right side called Rotch's notch; systolic recession is sometimes very striking where the effusion is large, but systolic recession in the epigastrium is at times well marked with adherent pericardium and it sometimes occurs without either pericardial adhesion or effusion in some cases of dilated right ventricle. The two signs yielded by percussion were Bamburger's sign, which is a small quadrilateral patch of dullness in the left interscapular space and the other is dullness over the lower lobe of the left lung posteriorly. Even with a large effusion and in the recumbent position friction at the base may be very loud. The diagnosis rests entirely upon the physical signs as there is nothing in the general condition or symptoms of the patient that is characteristic. It is from dilitation of the heart that precordial effusion had generally to be distinguished. The most conclusive sign is given by percussion; if the dullness can be shown to extend distinctly to the left and downward beyond where the apex of the heart is located the diagnosis is certain. With dilatation the impulse can usually be made out as far as the dullness extends at the apex and there is often a wavy impulse to be seen and felt in the left intercostal spaces above, unless the action of the heart be extremely feeble. The sounds also, though weak in both cases, may be completely absent with pericardial effusion, except perhaps at the base; with dilatation they are usually audible to some extent even down to the apex. The epigastrium is more prominent in large effusions. In pericardial effusion there is often systolic recession while in dilatation there is mostly systolic protrusion. Paracentesis is rarely necessary for serous effusions in the course of rheumatic fever. An exploratory puncture should be made first with a small sharp needle. The hand should be placed firmly upon the chest and the puncture made by the fingers rather than by a thrust of the hand and arm. The sites selected and advocated for puncture have been four: (1) In the third left intercostal space near the sternum—a dangerous place on account of the proximity of the left auricle; (2) in the fifth right intercostal space, to the right of the sternum—also risky; (3) the fifth space to the left of the sternum; and (4) the fifth or sixth intercostal space outside of the left nipple line but well within the area of dullness. This is the place Dr. West advocates and chooses. If exploratory puncture shows that there is purulent effusion the pus should be evacuated by paracentesis or by incision. He had seen some cases of purulent effusion cured in this way. Bearing in mind that pus in the pericardium may be in a pouch or pocket and not generally in the pericardial sac, it is well to leave the needle in and follow it down with the knife until the pus is reached.

A Singular Combination of Fractures of the Leg.—W. Arbuthnot Lane reports the case of a man in an athletic mood who arranged to jump over a flower-bed. He slipped, twisting his foot very painfully, as he approached it, and apparently leaping off the normal leg landed on the damaged one which he felt break with his weight. It seems pretty clear that the spiral fracture of the lower end of the fibula was broken by the excessive abduction of the foot, while the tibia yielded to the torsion to which it was exposed when he landed on the foot already over-abducted because of the fracture of the fibula. An upper fibular fracture was absent owing to the fibula having been already broken by the excessive abducion of the ankle. The treatmen of such torsion fractures consists in the free exposure of the tibial fragments, their accurate replacement in their normal relationship, and their secure fixation by one or more steel plates and screws.

A Case of Sudden Deafness Occurring During Eclampsia.—The only reported case of deafness arising during eclampsia is recorded by Macleod Yearsley. Two features of eclampsia may be pointed out: (1) that the symptoms are those common to many toxemias, and that eclampsia is, broadly speaking, an autointoxication by the toxic products of protein disintegration; (2) that eclamptic blood is characterized, among other things, by an increased coagulability. Deafness occurring during eclampsia may, therefore, be due to toxemia, to effusion or hemorrhage into the cochlea, or to thrombosis or embolism. The case reported he believes to be one of blocking of the cochlear branch of the auditory artery.

The Influence of Narcotics on Phagocytosis.—Leetham Reynolds records some experiments to show the effect of morphine on phagocytosis and it would seem that the morphine exerts a marked influence on the leucocyte. Not only does it check diapedesis, but phagocytosis is diminished in a marked degree, and the growth of the bacteria, on the other hand, is not appreciably affected. Morphine not only masks the symptoms, but it muzzles the phagocytes.

British Medical Journal, February 26, 1910.

Two Cases of Nonfebrile Erysipelas.—These two cases are reported by W. Cameron Macauley who states that they appear anomalous in that both, for the most part, had subnormal temperatures and in both the cerebral symptoms were early and profound, probably due to the fact that there was very little effort on the part of either patient to combat the disease—one being an elderly man of enfeebled constitution, and the other an infant three weeks old. In the old man, diarrhea was present, constipation being the rule. During the last four days before his death the temperature ranged from 97° F. to 97.6° F. The temperature of the body generally of the child was 97° F. Death occurred in this case.

Anasarca in an Infant.—John D'Ewart reports the case of an infant, ten days old, who developed a marked anasarca. There was an absence of all the usual causes of anasarca. A careful investigation revealed the fact that the nurse had added a quantity of salt to the food in the bottle, the exact amount of which could not be determined. The speedy recovery of the infant without any definite treatment, except the cessation of the salt administration, points conclusively to the salt having been the cause of the trouble. Considerable interest has been of late years exhibited in the question of the excretion of common salt from the body. This fact, supported by Widal's contention that a saltless diet is best in cases of renal disease, is ample excuse for recording this case.

Treatment of Suppurative Otitis.—Faulder White has performed several otectomies for the cure of suppurative otitis, and in every case a good result was obtained. He reports one case which is a fair example of the benefit to be derived from this very simple and safe procedure. A man about forty years old had suffered from an infected right middle ear for several years. His chief complaint was "stone deafness" on that side, with a distressing sensation of "deadness" as well. He could not hear a watch or fork at the meatus. He cleared out the middle ear and, as a result, he was able to return to his duty. All the unpleasant sensations he complained of had disappeared and he now could hear conversation with the right ear, though carried on in a low voice. The tick of the watch could not be heard at about three inches away from the right ear.

Berliner klinische Wochenschrift, February 14, 1910.

Rheumatic Polyserositis.—E. Mosler discusses this condition of simultaneous inflammation of the various serous membranes and summarizes his findings as follows: Apparently acute pericarditis and pleuritis are observed more frequently than previously, occurring as a sequel of a severe articular rheumatism or in rheumatic individuals in whom the arthritis lies in the background of the affection. Pleuritis and pericarditis come on suddenly and smultaneously. The severe discomfort, dyspnea, orthopnea, etc., are the result of the pericarditis. The pericarditis is usually dry, whereas the pleuritis goes on to a bilateral exudate. In a portion of the cases the pleuritis and pericarditis are complicated by an endocarditis, which may come on simultaneously or later. Myocarditis is observed in all the cases. The pleuritis usually recovers without nuncture, and with-

out extensive adhesions. The rheumatic pericarditis heals without clinically appreciable damage. The myocarditis accompanying the serositis often requires a longer time to recover and often leaves behind it a cardiac dilatation and a resulting metral incompetency. The prognosis is proportionally more hopeful the longer the time that has elapsed since the age of puberty

Testing Gastric Motility by the X-Ray.—E. Schlesinger says that the main objection which has been claimed against the testing of gastric motility by means of the *x*-ray, namely, that the bismuth gruel used as a test object in a short time sediments in the stomach, does not hold if a properly made gruel is used. The *x*-ray method exceeds all other known methods in exactness, can be used in almost every patient, and is the most agreeable to the latter.

The Prevention of Prolapse of the Iris After Cataract Operation Without Iridectomy.—Geis summarizes his results in operation on 170 cases of cataract extraction without iridectomy by saying that the instilling of a 1 per cent. solution of eserin immediately after the extraction without iridectomy markedly decreases the proportion of cases of prolapse of the iris. The eserin instillation certainly in no way interferes with the process of healing, but if anything aids it. The use of eserin as advised appears to increase the indications for extraction without iridectomy. Diabetes and nephritis are no contraindications to its use.

Münchener medizinische Wochenschrift, February 8 *and* 15, 1910.

The Tonsillar Treatment of Rheumatism.—Schichhold, in discussing the tonsillar origin of acute articular rheumatism, says that the exciting cause of the rheumatic disease lies in the pus filled tonsil crypts and from there may enter the circulation and produce the specific disease. Purulent collections in other organs besides the tonsils may be the source of the disease. Complete cure and especially prevention of recurrences is possible only by the most thorough removal of the tonsils. All other methods which do not accomplish this, especially the previously common tonsillotomy, are quite insufficient for a lasting cure. Besides the arthritis other complications also are influenced beneficially. Endocarditis and myocarditis can be cured only when they are in their earliest stage and no appreciable tissue change has taken place. Old verrucose nodosities are uninfluenced and are not only a direct hindrance to cure but a source of renewed infection. The tonsillar therapy has a favorable influence upon other diseases than rheumatism, which are associated with tonsillitis, especially upon nephritis.

Relation of Inflamed Tonsils to Infectious Disease.—Curschmann in describing this subject says previously disease of the tonsils was considered as a purely local condition. Recently its relation to infectious diseases has become appreciated. We know that tuberculosis may enter through these glands, and some claim that typhoid may also. It is probable that they may be the portal of entry for the virus of erythema multiforme, peliosis rheumatica, and similar conditions. Of especial importance is the relation of purulent disease of the tonsils to septic processes. The author believes that the diagnosis of many cases of "cryptogenic septicemia" would be cleared up if the tonsils were carefully examined. He has seen cases in which at autopsy tonsils but little enlarged and superficially apparently normal were found to contain tiny collections of pus, which were the cause of the severe disease. From these he has isolated streptococci, staphylococci, and pneumococci. Very frequently the cause of certain forms of nephritis are found to lie in a tonsillar inflammation. Simple tonsillitis, even without abscess formation, may cause acute or subacute, usually hemorrhagic, nephritis. This sometimes comes on very quickly after the onset of the tonsillitis, but more frequently is a sequela of the tonsillar disease. In every case of parenchymatous nephritis the history of disease of the tonsils must be carefully investigated as the disease may arise from the same tiny chronic abscesses. This is important therapeutically as well as diagnostically, as the author has seen recently three cases of tonsillar hemorrhagic nephritis recover rapidly after tonsillectomy. He believes that the nephritis is more frequently caused by toxines than by bacteria, though occasionally in such cases he has found pure cultures of the pyogenic bacteria in the urine and urinary antiseptics have produced prompt cures. He recognizes the close relation between tonsillitis and acute articular rheumatism, but believes that Schichhold has gone too far in saying that all cases of the latter disease are dependent upon the former.

Pneumococcus Septicemia with Hemoglobinuria.—Meyer reports the case of a young man who was taken suddenly ill with the symptoms of pneumonia. No pulmonary consolidation was discovered during life. He had a marked methemoglobinuria. The blood contained pneumococci and on centrifugalization the blood serum contained methemoglobin. At autopsy a small area of pneumonia was discovered in the lower lobe of the lung.

A Clinical Method of Estimating Uric Acid in Blood Serum.—Roethlisberger discusses the significance of uric acid in the blood and the methods of estimating it, all of which he says are unwieldy or inaccurate. He then describes his own method which is based upon the property of uric acid to reduce silver carbonate. The procedure must be carried out in a dark room with red light. On a strip of silver paper in a closed dish is placed with a fine pipette a small drop of 15 per cent. solution of pure sodium carbonate and the dish closed until the solution is completely absorbed by the paper. Then a drop of the patient's serum, obtained by the usual method of clotting a few drops of blood, is added from a second very fine pipette to the center of the moist spot on the paper. After two minutes in the closed dish the paper is removed and washed in clean water. After fifteen minutes the paper is placed for five minutes in a solution consisting of one part of pure ammonia and two to three parts of distilled water. The paper is then again washed in clean water for several hours, and then dried, after which it may be exposed to the light, though it does even then lose its color somewhat. If there is no uric acid in the blood the dried paper shows only a faint grayish spot. If uric acid is present this patch may be light red, reddish brown, or brownish black according to the amount of uric acid present. By comparison with a scale made by adding known quantities of uric acid to ox blood, the color tells the amount of uric acid present in the blood.

Treatment of Red Nevi by Light and Radium.—Kromayer has used either the quartz light or radium, or a combination of the two, in 40 cases of red birth marks, usually on the face. The light is indicated especially in the superficial cases of capillary nerves. The blue rays especially are advisable and a fairly high compression is required. The treatment lasts one-half and later one hour and occasionally even longer. A current of 120 volts and 3½ amperes is used. The use of radium is especially useful in the deeper arterial nevi. It produces a nearly painless inflammation of the skin, which heals in from 8 to 14 days, leaving atrophy of the skin. Most nevi are a mixture of both forms, and so the author has used the light treatment and followed it with radium. Of the 40 cases treated, but very few showed no improvement. The great majority showed improvement more or less marked. It was noticeable that most of the patients were more enthusiastic than the writer himself, urging him to repeated treatments. These repetitions, however, had a limit. He has never used the light on the same spot more than four or five times, or the radium more than two or three times. The light treatment is most effective at the first application; then it loses its potency, as it causes pigmentation, which absorbs the light rays and prevents further treatment. The repetitions of the radium are prevented by the danger of causing chronic dermatitis and teleangiectasis. Even in the favorable cases, with complete loss of the red color, it is only with the small superficial arterial nevi that the skin is left completely normal, so that the place cannot be told from the surrounding skin. With large nevi there is formed a slightly fibrous atrophic area with a whiter color than the surrounding skin. The indications for the treatment are: (1) Extensive red or blue-red nevi, provided they are superficial and due to capillary dilatation with slight arterial involvement, indicate light treatment; (2) the small red arterial nevi call for radium treatment; (3) the medium-sized mixed nevi, which make up the majority of nevi, demand a mixed treatment of light and radium.

"Floating Heads."—Longaker says that whenever a "floating head" persists until the advent of labor, difficulty, delay, and danger are to be feared, especially in the primiparous. Attempts to deliver by forceps are very likely to be unsuccessful, and they are frequently followed by the most serious consequences. Version, where slight disproportion exists, may be successful; likewise expectancy, delay, and then forceps; but in many of these cases the future welfare of mother and child will be best conserved by electing delivery by the abdominal route.—*Surgery, Gynecology, and Obstetrics.*

Book Reviews.

Les Maladies des Enfants. Par V. Hutenel, Professeur de Clinique Médicale Infantile à la Faculté de Médecine de l'Université de Paris, Membre de l'Académie de Médecine. Vol. I-V. Paris: Asselin et Houzeau, 1909.

This system of pediatrics from the pen of Professor Hutenel and his immediate associates is a most complete exposition of the theory and practice of the science of infant care and treatment as it is understood by the present school in France. Being the work of the professor and of his immediate disciples, it represents more of a unit than is common in treatises of its size, for not only did Hutenel oversee the work, but he took an interested part in the production of each chapter, as is attested by his name on each title page. While possibly some of its contents, especially that appertaining to the feeding of the infant, is at wide variance to the ideas most generally accepted in this country, nevertheless it represents the experience of a school of medicine which is acknowledged to be one of the best in the world, for France has long been noted for its pediatrists. Volume I, in which Lesné, Martin, and Darré collaborated with Hutenel, covers the general subjects of the anatomy, physiology, and hygiene of the child, the question of birth, heredity, and evolution, and their influence on the infant. The second portion of this volume contains the chapters on the infectious diseases. Volume II is prepared with the aid of Lereboullet, Bigart, and Tixier, and includes chronic infections, as tuberculosis, syphilis, rheumatism, and malaria, the diseases of the blood, and those of nutrition, as rickets. Volume III, in which the names of Nobécourt and Merklen are associated with the author's, covers the diseases of the digestive tract, the liver, the kidney, and the generative organs, and intoxication. To Volume IV Paisseau, Vitry, Leven, and Jeanselme contributed. It includes the diseases of the respiratory and circulatory systems and the skin. Volume V covers the diseases of the nervous system and in its production the author was aided by Babonneix and Voisin. To the reader of French the present system is of considerable interest and value. Placed upon the bookshelf for reference it is found to be a veritable storehouse of succinct, clear expositions of the various subjects included in pediatrics. It seems especially valuable in covering in a few words the various by-paths and rarities of the science and giving just the information wanted in exceptional instances in conditions entirely omitted or slurred over in the ordinary text-book of the diseases of childhood.

The Medical Complications, Accidents, and Sequels of Typhoid Fever and the Other Exanthemata. By H. A. Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College and Physician to the Jefferson College Hospital, Philadelphia, and E. J. G. Beardsley, M.D., L.R.C.P., Philadelphia. With a special chapter on the Mental Disturbances Following Typhoid Fever, by F. X. Dercum, M.D., Professor of Nervous Diseases in the Jefferson Medical College. Second edition, thoroughly revised and much enlarged. With 26 illustrations and 2 plates. Philadelphia and New York: Lea and Febiger, 1909.

Typhoid fever is always of interest to the physician, both because of its frequency and also because so few cases seem to follow the classical course laid down for them in the text-books. The present volume will prove a most useful companion to any treatise on Practice; and the practitioner will find here a full and authoritative discussion of the many medical complications, accidents, and sequelæ that are liable to occur in connection with this disease. Ample use is made of charts and illustrations; and the bibliographical references are unusually complete and up to date. Chapters are also added on similiar conditions occurring in smallpox, scarlet fever, measles, chickenpox, and rubella.

Principles of Hygiene. By D. H. Bergey, A.M., M.D. Third Edition. Philadelphia: W. B. Saunders Company, 1909.

In this, the third edition, Dr. Bergey brings his work up to date and incorporates the more important advances which sanitary science has made in the past four years. These advances relate especially to methods of sewage purification by biological processes, the defensive operations of the body and the best methods of rendering assistance to the same, the discovery of the cause of syphilis, the flea as an agent in the spread of plague, and other matters. The later editions of a book usually result in a presentation of its subject-matter in better form, and to this general rule Dr. Bergey's latest work is no exception. He unfortunately still attempts the impossible, however, by endeavoring to cover in 542 pages, nearly 100 of which relate to quarantine laws, the manifold phases of what is undoubtedly now recognized as being the most generally valuable, important, and extensive subject having to do with medicine. Necessarily much that should be common knowledge is left out of consideration, and some other matters receive such brief mention as to have their actual importance beclouded and belittled thereby. Examples might be given in failure to discuss the purification of water by ozonization, now an established procedure, and the dismissal of the tremendous specialty of military hygiene, which several volumes the size of Dr. Bergey's could not cover, in some eighteen pages of rather poorly selected matter. It has of course been a difficult task to make a judicious selection of material for incorporation in this book, and it seems to the reviewer a mistake on Dr. Bergey's part apparently to have attempted in advance to crowd the consideration of a broad science into a definite number of pages, rather than to let the number of such pages be determined by the actual needs of such proper consideration itself. As it is, the text gives the impression of excellence in every way, except for a certain feeling of insufficiency and incompleteness dependent on a somewhat too brief and dogmatic handling of its various subjects. The illustrations in the book are not many, do not seem to have been well chosen with a view to their practical value, and take up valuable space which, if there is any valid reason for keeping the book at its present size, might better be used for other purposes. In its printing, binding, and general get up the book leaves nothing to be desired.

The Causation of Sex. A new theory of sex based on clinical materials, together with chapters on the forecasting of the sex of the unborn child, and on the determination or production of sex at will. By E. Rumley Dawson, L.R.C.P. London, M.R.C.S. England; Fellow of the Royal Society of Medicine, Late Member of the Council of the Obstetric Society of London, formerly Resident Obstetric House Physician to the Westminster Hospital. London: H. K. Lewis, 1909.

Dr. Dawson's hypothesis states that sex is not influenced by the male, but depends upon which ovary supplies the female elements. That is, a male fetus is the product of a right ovary plus a spermatozoon, and a female fetus is the product of the left ovary plus a spermatozoon. The right ovary is larger than the left (William Anderson, Clarence Webster, G. A. Piersol, Parrein, Bonamy and Bean, Berry Hart, and other anatomists), therefore more boys are born than girls since the area of ovarian tissue is greater in extent and produces more ova. Moreover extirpation of both ovaries has resulted in sterility; of the right ovum, in girl progeny, and of the left ovum, in boy progeny exclusively. Ovulation alternates regularly, thus if the right ovary casts off an ovum in December, the left will do so in January, the right in February, the left in March, etc. Hence one can calculate the sex of any expected child, the year, month and day of the first born being given, and the author claims 97 per cent. of successes in his predictions. This statement is not exactly in accord with the previous one that the right ovary produces more ova than the left. Certainly the scheme is ingenious and deserves wide attention on the part of obstetricians in order that more facts may be adduced.

Diseases of the Nose, Throat, and Ear. By Charles H. Knight, M.D., Professor of Laryngology, Cornell University Medical College; Surgeon Manhattan Eye and Ear Hospital, and W. Sohier Bryant, M.D., Senior Assistant Surgeon, Aural Department, New York Eye and Ear Infirmary. Second Edition, Revised with 239 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

This is really the second edition of Dr. Knight's portion of the work, with a new part on otology added by Dr. Bryant. The chief additions to the former edition are in the chapters on deviated septum and diseases of the accessory sinuses. In regard to the method of direct examination of the upper air passage the author of the first part says that not too much attention has been given to the subject because it is not likely that the older methods of examination will be supplanted as a matter of routine, for the class of cases within its scope offers a comparatively restricted field for the new procedure. In the second place the apparatus and the unusual operative skill required are more or less prohibitive as to general use. Nothing of importance is, however, omitted. In response to many requests a new part on otology has been added. The well-known experience and clinical activity of Dr. Bryant are responsible for many new and instructive illustrations and an interesting text.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 17, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THE papers and discussions were devoted to a symposium on thoracic surgery.

The Method of Respiration by Continuous Intratracheal Insufflation: Its Theoretical Significance and Its Practical Availability in Medicine and Surgery.—Dr. S. J. MELTZER read this paper. (See page 477.)

Avoidance of Apparatus Complicating the Operation: A Paramount Requirement in Thoracic Surgery.—Dr. WILLY MEYER read this paper. (See page 483.)

On Experimental Intrathoracic Surgery by the Meltzer Method of Intratracheal Insufflation.—Dr. ALEXIS CARREL read this paper. (See page 491.)

Demonstration of an Apparatus for Continuous Intratracheal Insufflation, with Remarks on the Use of This Method in Thoracic Surgery.—Dr. CHARLES A. ELSBERG read this paper. (See page 493.)

Dr. SAMUEL ROBINSON of Boston said that doubtless there was a temptation on the part of many to credit him with a special fondness for his own apparatus for use in thoracic surgery, and it was true that he had adopted a form of apparatus, but only after having given other forms of apparatus used in thoracic surgery a fair trial. It was his good fortune in the spring of 1908 to hear a gentleman of Cleveland describe his procedure in which a tube was introduced down to the bifurication of the trachea through which he was enabled to continue the oxygenation of the blood without disturbing the heart beat. After some correspondence with this gentleman Dr. Robinson repeated his experiments and was greatly interested to learn that by the use of intratracheal injections with the catheter, even with the lungs in a state of practically complete collapse, oxygenation of the blood was kept up. It then occurred to him that surgical operations might be performed with the use of this method, and this led to further experimentation, doing operations upon the thorax with the lungs practically in a state of collapse. He was led to attempt to use air instead of oxygen in the same way, but found that he could not keep up the function of the heart beat with air without keeping the lungs in a state of at least semi-inflation. He finally concluded that, in order that the function of the heart should be kept up, the lungs should be in a state of two-thirds inflation. This fact he did not bring out with any idea of claiming priority in any way, but to show that he had continued his work with other methods; his chief reason for changing was primarily that he could see no occasion in surgery where the entire front of the chest would have to be removed. He also realized that in practically every operation one could think possible on the human, one side of the chest only was opened. In further experimental work they placed in a straight tube, the walls of which completely filled the larynx, but it was found that oxidation was not kept up and dyspnea ensued. Alterations were made in this tube and further experiments made, but they soon realized that this could not be utilized in thoracic surgery on the human being. He had been led to believe from what he had been told by the nose and throat specialists that the maintenance of any foreign body in the trachea was not an easy matter; even when the parts were cocainized, and the tube introduced, to again cocainize the parts the tube must be withdrawn and this was not feasible; when once the tube was introduced into the trachea, it must not be removed; the reintroduction of the tube in the middle of an operation might cause some confusion. Dr. Robinson thought it was well to introduce new apparatus. While in Europe he had seen most of the famous apparatus in use, and he had himself come to use what he termed the classical apparatus; in fact, he had both the so-called classical and the emergency apparatus, the latter being supplied with a mask. It was interesting to note that in dogs bronchitis, tracheitis, or pneumonia was not caused by etherization by this method and he was led to believe that the resistance in dogs to these conditions was greater than it was in the human being. These things should be borne in mind in order that they might be just in their criticisms of the various apparatus which bid fair to introduce a new surgical technique. Dr. Robinson said that his clinical experience had taught him that it was best to use some simple apparatus, not necessarily a small one, but one which, even though a clumsy affair, could be run by a person who knew the least about such apparatus in hospitals. Small apparatus, as a rule, was quite complicated in its construction, while with the larger types the surgical operation could be run smoothly and rapidly.

Dr. HENRY H. JANEWAY said that during the past two years Dr. Green and he had worked together in intrathoracic surgery, and both of them had taken a deep interest in Dr. Meltzer's work because of its close similarity to the method of artificial respiration formerly used by Dr. Green. This method consisted in the inflation of the lungs with air interruptedly passing to them from a constant pressure in a tank and through an intralaryngeal tube. Provision was made for the escape of air from the lungs in the intervals between the inflations through an opening in the part of the tube within the mouth of the animal. Dr. Meltzer's method was an improvement upon the method of Dr. Green in that a soft rubber catheter was used instead of a rigid tube and, secondly, in the fact that this tube was passed further within the trachea. The method was the same that Robinson tried and published in 1908. It seemed to him that the important feature in this method was the fact that when a tube of sufficient size was passed within the trachea, the larynx so hugged this tube that considerable resistance was offered to the outcoming air. Undoubtedly the failures to appreciate this fact explained why the method had not been used before. The contention, however, must be true, because Dr. Meltzer used a pressure of some fifteen to twenty or twenty-five mm. of mercury in the tube, while the degree of distension of the lungs showed that within the trachea there must be a pressure of at least 5 to 8 mm. The method, therefore, was a true positive pressure method and all that Dr. Meyer had said regarding this point and the fact that the tube within the trachea must be considered an additional complicating factor was true. Dr. Janeway had had the opportunity of operating by Dr. Meltzer's method at the Rockefeller Institute with his own apparatus, and the operation passed as smoothly as any that he had ever performed. The artificial respiration continued perfectly even from start to finish. The respiratory movements of the animal were not entirely eliminated. In fact, concerning this point he could observe no difference between the method and one formerly used by Green or the one which they were now using. In fact, Dr. Meltzer encouraged the periodic deflation of the lungs by every now and then exhausting the air from his system of tubes. The frequency with which this must be done depended upon how extensively the thoracic cavity was opened. If both sides were opened, or if the method was used to artificially respire a patient suffering from paralysis of respiratory center due to too much ether or a toxic dose of morphine, the frequency of deflation of the tubes must correspond to normal respiration. It seemed, therefore, that for this reason also the method was a true positive pressure method. Now, whether the presence of a tube in the trachea could be a harmful addition or complication in positive pressure artificial respiration Dr. Janeway did not think could be de-

cided without extended trial. The only objections which he could think of were purely theoretical. They were four in number and were the very ones which influenced Dr. Green to suspend the use of his intralaryngeal canula. In the first place, the necessity for the introduction of a tube within the trachea would be found inconvenient in many instances, particularly in use in the fire department as in cases of suffocation by smoke, and in cases where it was necessary to have nurses or physicians unfamiliar with intralaryngeal work use the method. Secondly, the presence of a tube within the trachea might be found inconvenient and in the way during attention to the toilet of the mouth and in such intrathoracic operations in which instrumentation of the esophagus was needed. Thirdly, they believed that more ether was absorbed by the patient when administered through the intratracheal tube. Dr. Green was certain that this was true from his own experiments and this fact was one of the most important considerations which influenced him to suspend its use. There were two reasons why this was so. The first was the fact that in positive pressure applied by a cabinet a certain amount of cerebral anemia existed. Sauerbruck had utilized this fact in cerebral surgery. This cerebral anemia rendered less ether necessary. The second reason depended upon the completeness with which the patient was artificially respired. It was difficult to judge of how much ether the patient was receiving. Dogs by this method could receive what would otherwise be a toxic dose. They believed that such an intoxication must increase the shock of intrathoracic operations. Lastly, it might not prove impossible that in certain pulmonary conditions the presence of a tube in the trachea and stream of ether vapor directly upon the bronchi might be deleterious.

Dr. William W. Keen of Philadelphia said that after having seen Dr. Carrel operate, manipulating the viscera of the chest with the same ease and exactness as one would in abdominal surgery, he was delighted with the whole thing and that if it was necessary to operate upon his own lungs or upon his aorta the Meltzer and Auer method would be his preference. The method was simplicity itself and he was very much impressed with it. When he wished to close the cavity of the chest the pressure was increased at his request a little, so that the lungs expanded and obliterated the chest cavity and there could be no pneumothorax. The respiratory function was reestablished in the animal one and a half hours after the operation, after a transverse section of the chest had been made, both cavities having been opened. What he had seen Dr. Carrel do was to him a revelation.

Dr. William S. Halsted of Baltimore said that for a year or more he had been interested in thoracic surgery and until Dr. Meltzer had described his method he had used the positive pressure apparatus because he had no negative one. In his experiments upon dogs the Meltzer-Auer apparatus had been used with the greatest satisfaction, and even if it had not yet been used on the human subject it was a wonderful contribution to their animal work. Having worked with positive pressure apparatus of various forms, as well as incubation tubes, etc., it seemed to Dr. Halsted that the Meltzer-Auer apparatus was one of simplicity. He sympathized with Drs. Willy Meyer, Robinson, and Elsberg in what they had stated, and he felt that it was true; at the present time it was too early for one to be justified in speaking positively in regard to any one apparatus of the pressure sort; time only would determine its value. In his clinic in Baltimore Dr. Halsted used nitrous oxide, carbon dioxide, and oxygen gas, and when these gases were given in their proper combination, the patient went under the influence very easily and, even after very prolonged operations, within five minutes they were conscious. He reported some cases in which the operations were very prolonged and, with the use of these gases, consciousness returned within a few minutes after the operation. Then, too, the condition of these patients after taking these gases was entirely different from the condition of those who took ether. In old alcoholics sometimes ether had to be supplemented. Before he had used these gases he said he did not realize how detrimental the use of ether was.

Dr. Joseph C. Bloodgood of Baltimore said that perhaps in the future the progress in surgery must come from the experimental laboratory and perhaps in the surgery of the thorax they had better evidences of the importance of experimental surgery; the progress in this work must be made in the laboratory. As a rule, in the majority of the cases in the past history of surgery, what had been established in animals in the laboratory had been shown to apply to human beings, and that was one reason why he believed that this simple method of anesthesia in thoracic surgery would eventually become practical.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 10, 1910.

Dr. Eli Long in the Chair.

A Case of Intussusception.—Dr. Edward W. Peterson presented a patient who, when five months old, was admitted to the Post-Graduate Hospital. Two days before admission the baby seemed to be suffering from abdominal cramps; there was vomiting at frequent intervals and the bowels did not respond to the giving of enemata. On the third day, however, blood and mucus were expelled, unaccompanied by feces and flatus. The abdomen was moderately distended and very rigid. An elongated mass was felt on the left side. The examining finger when withdrawn from the rectum was covered with bloody mucus. A diagnosis of acute intussusception was made, and this was confirmed at operation. It was of the ileocecal variety. Owing to the edematous and friable condition of the gut, adhesions having formed at the neck of the intussuscipiens, it was very difficult to reduce the last two inches of the invagination. The bowels acted naturally on the second day. The secondary enteritis yielded to appropriate treatment. The patient was discharged on the seventh day.

A Case of Tuberculous Peritonitis.—Dr. Peterson presented a boy, three years old. In February, 1908, he had a very severe attack of gastroenteritis, which lasted three weeks. Shortly after this the boy very slowly lost weight and strength, and at the same time there was a gradual increase in the size of the abdomen. Several physicians out of the city examined this child and pronounced the condition a malignant one and gave a grave prognosis. This weak and emaciated child was admitted to the Post-Graduate Hospital with the skin and conjunctiva jaundiced, and with a bronzing of the skin over the abdomen suggestive of disease of the suprarenals. Nodular masses were readily palpated in the abdomen and one, the size of an orange, was distinctly felt to the left of the umbilicus; they were most prominent in the right iliac region. There were 2,360,000 red cells, 8,000 leucocytes, 55 per cent. hemoglobin; the polymorphonuclears showed 33 per cent., the small lymphocytes 60 per cent., and the large lymphocytes 7 per cent. After studying the case for a few days they decided they had to deal with a case of tuberculous peritonitis. Treatment with fresh air, tonics, etc., was tried for three weeks, but as the child was losing weight and strength it was decided to operate. A two-inch incision was made in the abdomen and a very extensive miliary tuberculosis was found. The fluid evacuated was very suggestive of an old hemorrhagic condition. The parietal peritoneum, the in-

testines, omentum, and other parts were simply studded with innumerable miliary tubercles. After washing out the cavity with peroxide of hydrogen, then with normal saline solution, the wound was closed without drainage. The parents were carefully instructed how to carry out the hygienic and tonic treatment properly. In addition inunctions of mercury were given. The discoloration of the skin soon cleared and to-day the boy was apparently in perfect health.

Intussusception.—Dr. JOHN F. ERDMANN read this paper. In his series of operations, now about forty-five, he said he had been struck by the health of the patients, few having been ill before the onset of the trouble. The onset was sudden, with colicky pains, accompanied with shock; this primary onset was followed by cramp-like pains, intermittent in character. The early shock disappeared as the first hour passed. The diapers were likely to be slimy and contain blood. This evidence of blood was pathognomonic when there was a previous colic, shock, and spasm picture. Frequent desire to defecate, tenesmus with little result except quantities of mucus and blood, vomiting, and distension of the abdomen were developed in the order named. In the majority of the cases palpation failed to reveal a tumor, and certainly not the classical sausage-shaped one described in the text books. The rectal examination revealed a tumor far less often than abdominal palpation, unless the case be of a day or more duration; the withdrawal of the finger from the rectum was followed usually by blood and mucus. The abdomen was lax during the early hours of the disease, but subsequently became distended. The pulse was accelerated. The temperature was usually subnormal or normal at the onset, but a moderate rise ensued during the progress of the disease. The differential diagnosis of these cases sometimes was very difficult, especially those cases with visceral crises in the erythema group of skin diseases. Little difficulty should be met in making a differential diagnosis in a case of appendicitis. In considering the treatment he inserted, with a few alterations, a portion of a paper published in the *New York Medical Journal* in May, 1904. In his last sixteen cases of operative reduction the average age was six and a half months, the youngest being sixteen weeks old, with males in excess. One of these cases died, the cause being in all probability status lymphaticus. All of the excision cases died. In conclusion Dr. Erdmann said that early recognition of the condition was absolutely necessary to a high recovery rate. Inflation was decidedly not useful, but dangerous. Enemas were successful in an exceedingly small proportion of the cases, and should not be used after six hours. The earlier the operation, the more likelihood of a small mortality. Late operations might be followed by gangrene with all its horrors.

Appendicitis in Infants and Children.—Dr. CHARLES N. DOWD said he wished to refer to a few points which hinged upon two questions, when to operate and how to operate. The diagnosis in children was very difficult and because of the repeated consultations and the consequent delay there occurred often a general spreading peritonitis with fatal results. Murphy of Chicago had called attention to four important symptoms in acute appendicitis which followed as a sequence; if they did not follow as a sequence the diagnosis of appendicitis might be questioned. (1) Pain in the abdomen, sudden and severe; (2) nausea and vomiting, usually three or four hours later; (3) abdominal sensitiveness most marked in the appendicular region; (4) moderate elevation of temperature from two to twenty-four hours after the onset of the pain. The first, second, and fourth symptoms were of little significance in children except as confirmatory of the third. One was, therefore, often misled in making a diagnosis of appendicitis in children, and must depend mainly upon the third symptom. Muscular rigidity, which indicated this tenderness, was as definite in children as it was in adults. It was not, however, so definitely localized since children's appendices were relatively longer than adults, and the rigidity might vary with the position of the appendix. There were several distinct inflammations which were apt to make a differential diagnosis difficult. Amongst these were the following: 1. Beginning pneumonia. Occasionally adults with a commencing pneumonia would give symptoms very suggestive of an appendicitis, but in children this occurred frequently. 2. General peritonitis from unknown causes. Children were very apt to have a spreading peritonitis from an unknown site of infection, which spread very rapidly and usually with a fatal termination. This form of peritonitis was found more often in children than in adults. 3. Tuberculous peritonitis. This was common in children and often simulated appendicitis; it was usually the form with plastic exudate and not the ascitic form found in adults. 4. Pneumococcus peritonitis. 5. Gonococcus peritonitis. 6. Cyclic vomiting. This form often gave symptoms much like those of appendicitis. It was interesting to note that Comby of France had operated upon many of these cases, believing them to be a chronic form of appendicitis, and a large proportion of the cases seemed to have been cured by the operation. 7. Foreign bodies. Dr. Dowd said that he had taken three pins from the appendix and in one case he found a round worm free in the peritoneal cavity, with no indication of the point of exit from the intestine. 8. Hip disease. Whatever ideas one might have in regard to the time of operation in appendicitis in adults, when dealing with children all ideas of delay should be thrown aside. One should operate as soon as the diagnosis was made. Children were more apt to have a spreading peritonitis with appendicitis than were adults. The mortality had been very high, but last year George Alsberg reported sixteen cases occurring in children without mortality. Dr. Dowd's mortality rate was as follows: In a group of 70 cases, of whom 15.7 per cent. were operated upon at an early date, 57.1 per cent. later, and 27.1 per cent. in the interval, the mortality was 10 per cent. In a second group of 50 cases, of whom 16.0 per cent. were operated upon at an early date, 74.0 per cent. later, and 10.0 per cent. in the interval, the mortality was 8 per cent. In a third group of 61 cases, of whom 36.1 per cent. were operated upon at an early date, 49.2 per cent. later, and 14.7 per cent. in the interval, there was no mortality. A child under two years of age did not stand as good a chance as one over that age, yet these young children would do well if one could make an early diagnosis and did not attempt too much at the operation. It was the difficulty of diagnosis rather than the question of operation which made the mortality rate so high for little children. They stood the simplest operations wonderfully well.

Dr. EDWARD W. PETERSON believed that there was no type of intestinal obstruction so easy to diagnose as intussusception. An acute invagination usually manifested itself in a subject whose previous health had been good. The onset was sudden, with severe paroxysmal colicky pains, vomiting, straining, and mucohemorrhagic stools. There was constant desire to go to stool, with a passage of mucus and blood, without feces or flatus; this was pathognomonic of intussusception. If, in connection with the symptoms just mentioned, a cylindric or rounded intestinal tumor could be felt, then the diagnosis was rendered reasonably certain. It

might be added that in cases of intussusception a careful examination of the abdomen and rectum, under an anesthetic if necessary, would generally reveal the presence of a tumor. Dr. Peterson said he had operated upon nine cases and had seen as many more, and in every case a tumor could be felt. In intussusception the prognosis was going to depend not so much upon the duration of the affection as upon the amount of obstruction and the degree of strangulation to the blood supply of the invaginated gut. He agreed heartily with the recommendations for treatment as outlined by Dr. Erdmann. In discussing Dr. Dowd's remarks he said there was no question about the difficulty of making a diagnosis of appendicitis in infants and young children. He was surprised at a mortality of 30 per cent. given by a certain Brooklyn surgeon in discussing the subject. In the wards of the Post-Graduate Hospital he had lost but one case during the last seven years. Children stand the operation remarkably well, if one was careful not to attempt too much.

Dr. Godfrey R. Pisek, in discussing Dr. Dowd's paper, said that no reference had been made to one method that was a great help in diagnosing appendicitis in children, that was rectal examination. Children stood this examination well and an enlarged appendix or an abscess could be palpated and located especially if the bimanual method were used. This method had not been used as often as it might have been. Dr. Pisek cited the case of a child of a physician who had cyclic vomiting and was operated upon for a subacute appendicitis. Since the operation she was much improved under the same treatment as before the operation. This was in accord with what Dr. Dowd had said in regard to cyclic vomiting.

Dr. Sara Welt-Kakels said that she had been impressed by the fact that in some cases of intussusception there was absence of pain, mucohemorrhagic stools, and tumor, and she believed that the general practitioner, in treating cases of gastroenteritis, should think of the possibility of intussusception, even in the absence of some of the well-known cardinal symptoms. Dr. Welt-Kakels cited the case of a child being treated for gastroenteritis, who was brought to Mt. Sinai Hospital because the mother did not think proper progress was being made; by means of a rectal examination she had made a diagnosis of intussusception. At operation a loop of gangrenous intestine was found. The child died twenty-four hours after the operation.

Dr. William P. Northrup said that he taught his students that there were three things about which they should always be very keen from the time they graduated until they quitted their calling; these were the diarrheal diseases of summer, pneumonia, and intestinal obstruction. He had seen two cases of intussusception within two weeks, some time ago, both of which were injected with water and both got well. This was the worst thing that could have happened to him, for he had written a paper about the results. Since that time he had learned better and preferred surgical incision. Shortly after his experience with the two cases that were cured by injection, he had seen a case at the Presbyterian Hospital in which the question arose whether to inject water or make an incision. The incision was decided upon and an intussusception was found in which it was very difficult to draw out the gut, especially the last portion. Dr. Northrup cited the case of a robust child with an inordinate appetite, who ate almonds and meat. He began to have pain, became very ill, and vomited excessively. For three weeks he went on in this way. Dose after dose of castor oil was given, each followed by a watery discharge. Finally a practitioner said: "Give him rhubarb and soda; if without effect, give it again and again." This was done and finally the child passed a large, putrid bolus, which contained, among other things, almonds. The child had been well since. Dr. Northrup cited two other cases in which the appendix was found to be in an abnormal position. In one instance it had become wrapped around the bladder and in the other it was tucked up behind the cecum.

Dr. Dowd closed the discussion. He said that in his experience the leucocyte count had been a very indefinite guide. He had operated upon abscesses where there was a 36 per cent. polymorphonuclear count; in several where there was a low differential count and occasionally there was a low leucocyte count, while in very many cases with no discoverable lesion there was a very high leucocyte count. Probably in the majority of cases the leucocyte count would correspond with the condition found, but there were so many exceptions that he could not interpret and he knew of no one who could. The presence of calculi was another trap that might very easily mislead one. He had never seen a ureteral calculus occurring in a child, although since they occurred in the bladder he supposed they also occurred in the ureter. He had never found rectal examinations as valuable as the abdominal examinations, although he regularly made them. The abdominal muscles were a telltale and he found no structure by rectal examination that gave an equal amount of information.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 31, 1910.

The President, Dr. John E. Weeks, in the Chair.

Address of the Retiring President.—Dr. H. Seymour Houghton delivered this address. He thanked the members of the society, and expressed his appreciation of the uniform courtesy extended to him in his efforts to properly conduct the proceedings of the society, and in maintaining its scientific work and upholding its dignity as one of the leading as well as one of the largest medical organizations in the City and State of New York. Entering the office as President with a degree of fearfulness that was somewhat terrifying, and leaving it with regret and a happy retrospect, he said he could appreciate the mental process involved in the popular idea, as expressed in their pictures of the New Year, where it was possible for the year to be ushered in a stripling baby and in a short twelve months to step forth from activity a gray-bearded old patriarch. The attendance upon the meetings had been remarkably great. The papers read had been both interesting and instructive, and unquestionably had punctuated the progress of medicine. While the evenings had been extremely long, at times running well on toward midnight, they had been all too short for full justice to be done to the papers or proper discussion to be had on the valuable points brought out. Dr. Houghton felt that it would be most fitting to take some action looking toward regulating their executive sessions, especially in such a way that undue prolongation of the business features should not occur. He called attention to the conscientious and thorough work of the members of the Comitia Minora and the painstaking and judicial care exercised by their counsel, Mr. Vandiver, in matters of dispute between fellow members; he said he also bore witness to the brilliant and admirable management of their finances by the treasurer, Dr. Richardson; no less efficient, no less painstaking, and no less difficult had been the work of the secretary, Dr. Young. During the ten years of his incumbency he had brought the work of his office to a state of systematic development out of all proportion to the early requirements; one glance

at his office would be almost enough to discourage one from wishing to be a successor when Dr. Young became weary of the strain. Dr. Houghton told of the work of the Milk Commission in connection with the Health Department in general, and with that of Dr. Park in particular. Recently a small outbreak of typhoid fever occurred over in the East Side. By a process of exclusion the source of this outbreak was traced to a small town, Salem, up near Saratoga, and there to a particular dairy, and finally to no less a person than the owner of the dairy, an old gentleman found to have been a typhoid carrier dating back some forty years. This was but a small item.

Inaugural Address of the President.—Dr. John E. Weeks said that the possible activities of this society had an exceptionally broad scope; they were "to aid in regulating the practice of medicine and surgery in this State, to contribute to the diffusion of true science, particularly the knowledge of the healing art, and to assist in the preservation of the public health." Theirs was the oldest incorporated medical society in the State. It was first known as the Medical Society of the State of New York, and began its work November 14, 1794. About twelve years later (April 4, 1806) it was incorporated as the Medical Society of the County of New York. The society had grown until now its membership was approximately 2,325, a little more than one-third of the entire membership of the State Society of which it formed a part. Among the many advantages accruing to membership in the Medical Society of the County of New York were the scientific work of the stated meetings, the protection against suits for alleged malpractice, the prosecution of the quack and charlatan, the receipt of the directory and the State journal, membership in the society, and eligibility to membership in the American Medical Association. In the County of New York there were about 4,667 regular physicians, of which number about one-half were members of the society. One of the important objects of the society was to assist in the preservation of the public health. Under the direction of the Board of Censors their counsel had during the past year instituted proceedings against fifty-three medical corporations and individuals who were practising medicine or vending nostrums illegally, and many convictions had been obtained. The report of the treasurer on November 19 last showed a balance for the year of $3,000.79; this, with the funds on deposit, made a total cash surplus of $8,205.74. Last year 225 bills having some medical import were introduced into the State Legislature; of these seventeen became law. Fortunately, few, if any, of the bills passed were detrimental to the community or to the medical profession. The Committee on Legislation, in connection with similar committees in the county branch and State societies, backed by the membership of these bodies, were able to exert a strong influence on the Legislature. It was the firm opinion of all medical men of the State who had studied the subject of animal experimentation that the present restrictions by law in this State were sufficient to prevent undue suffering on the part of the animals employed and to confine experiments within reasonable limits. Since this was the case, it became the duty of the society to lend its energetic support to the effort to defeat the enactment of laws designed to further restrict or embarrass animal experimentation.

The Appropriation of Public Funds for the Partial Support of Voluntary Hospitals, with Special References to the Development of the Hospitals of the City of New York.—Dr. S. S. Goldwater opened the discussion on this subject, and said that there were a great many reasons why the members of the society and the medical profession of the city should interest themselves in those phases of public law which directly or indirectly affected the hospitals of the City of New York. So far as the principal question under consideration was concerned, he called attention to the fact that of the 14,000 hospital beds for all classes of cases, 70 per cent. were to be found in the private hospitals and but 30 per cent. were to be found in the municipal establishments that were supported by public funds. Dr. Goldwater asked those present if they favored the voluntary hospitals or the municipal hospitals if this question was to be voted upon. When questions of this sort came up for consideration he believed that the officials and city legislators had a right to expect co-operation and guidance on the part of members of the medical profession. They should all know just what the hospitals were doing, what they were accomplishing, and just what they failed to accomplish. At the present time the hospital system was in an undeveloped state. In New York City alone there were 350 beds for each 100,000 population. Something might be accomplished if they could give the legislators a clear idea of the relation the hospitals bore to the community of the city and State, as well as a clear idea as to what constituted a perfect or ideal hospital. The latter was not to be found in this country. He advised against their becoming extremists without knowing just what constituted a good hospital. What was greatly needed were hospitals that would do the work intended by them properly. They should all welcome voluntary support to hospitals as something by which the burden on the taxpayers would be reduced. They should welcome such support, and not reject it. A co-operative system was characteristically an American system; in thirty-five States there were laws under which this sort of co-operation might be carried out. New York State had a system which was a good one; Pennsylvania, on the other hand, had a system which was as bad as New York's was good. There were several hospitals in the City of New York that refused to apply for city appropriations; yet they made no bones about accepting exemption from taxation. He knew of 200 vacant beds in certain of these hospitals—vacant because they did not have money enough to support them. Yet the city was knocking at their doors ready to aid them if they would accept. These institutions declined such aid through fear of city or State interference; they objected to the public officials. At Mt. Sinai Hospital such an objection did not exist. They were not ashamed of their institution and were not afraid of any inspection by public officials. The City of New York was not obliged to appropriate a dollar to the hospitals; such an appropriation was not mandatory. The Board of Estimate and Apportionment had adopted a very comprehensive set of rules; they determined the maximum amount of money the city was willing to set aside for the purposes in question. In 1907 Mt. Sinai Hospital expended over $384,000, and received from the city $54,000. The Lying-In Hospital spent some $39,000, and received from the city $17,000. The Post-Graduate Hospital spent $189,000 and received from the city but $16,000. These were merely a few examples. There were all told forty-one hospitals that spent about $3,000,000 and received from the City of New York $209,000. It was, therefore, very evident that what the City of New York appropriated to these institutions represented but a small proportion of the actual cost of maintenance.

Mr. John M. Glen, secretary and director of the Russell Sage Foundation, told of his twenty years' valuable experience in dealing with hospitals and charity organizations in his native State, Maryland. For years he was a member of the tuberculosis commission. He said he was astonished at the amount of money going out for charitable affairs. This whole subject must be considered from a very broad point of view. He did not believe it was the function of the government to administer charity; relief by the State or city was not charity at all; it was merely relief. Public and private charities should be kept distinct from each other. He asked what the State was doing in regard to public health, that was, in regard to preventive measures.

Was it doing its duty in the realm of public hygiene? He asked that they listen to some figures from the State of Pennsylvania showing appropriations to hospitals; 140 institutions received from that State over $4,500,000. Just think what could have been accomplished if they had spent that amount of money on public hygiene or anything else but the public hospitals. Think of what could have been done in educating the people about tuberculosis. Think what could have been accomplished in Pittsburg. A great deal could have been done in factory inspection. Mr. Glen then gave some facts that concerned the State of Maryland. He believed the fact alone that the city gave money to institutions tended to a multiplication of these institutions, many of which were unnecessary. Private money could be obtained when the institutions failed to get money from the legislators. Reputable citizens, good men and women, as well as reputable doctors, asked for appropriations for the benefit of private institutions, thus saving the trouble of asking for appropriations from benefactors.

Mr. Homer Folks, Secretary of the State Charities Aid Association, said that he fancied that he had been asked to participate in the discussion of this subject because he was supposed to belong to one of the "extreme" classes, namely, to those alleged to be opposed to granting public money to private institutions. His own instinctive feeling toward this subject was perhaps best illustrated by recalling the remark of the Kentuckian in reply to some reference to bad whiskey. He corrected the speaker, saying that no one should speak so disrespectfully of such a desirable product; that some whiskey might be better than other whiskey, but there was no such thing as bad whiskey. All hospitals looked good to him; some were better than others; but all hospitals, honestly established, did a great deal of good. He said frankly that the hospital with the most money looked best to him. The hospital that had the means to take care of its people well, to give them plenty of good food, to provide good nurses, and to supply good instruments in the operating room looked best to him, irrespective of the particular form of its management. Respectability of managers, good intentions on their parts, or even religious zeal were poor substitutes for the wherewithal with which to pay bills. The question turned not so much on the saving to the taxpayer as on what system would, in the long run, secure for them the largest number of adequately equipped, adequately maintained, and wisely maintained hospitals. It was probably unfortunate that this function had not yet been clearly defined in the range of the duties of the municipality or of private charity. The public hospital had grown upward from the almshouse; the private hospital had dropped down from the skies of benevolence. They had not as yet found their perfect adaptation one to another. The subject might be discussed in two ways: first, on what they would think best for a locality starting anew, or, secondly, they might discuss what was best from now on for the City of New York. These two possibilities should be kept clearly in mind, for what was best for a new community might not be most practical for a city already encumbered with traditions. If they were starting afresh he would draw a clear line between public and private hospitals and would devote no money derived from taxation to the maintenance of any private institution whatever. In order to illustrate his point he cited what had been done along educational lines, and said he doubted if we would have such an effective school system if the schools had been dependent upon public charity. Likewise it was possible that had the municipality been responsible for the hospitals from the beginning there would be a much better hospital system than now existed. The fundamental objection of the present scheme was the division of responsibility. Mr. Folks agreed with Dr. Goldwater that the New York system of regulation was by far the best system that had been devised in the United States. A study of four or five individual hospitals during the period from 1897 to 1908 showed that city appropriations had increased, but that this increase bore no definite relation to the private contributions. Taking the system as a whole, that was, hospitals receiving aid from the city during that period of time, private contributions increased from $460,000 to $835,000. City appropriations increased from $130,000 to $680,000. In another year the city appropriation will have passed in actual amount the receipts from private contributions. These results did not seem to show that they had yet found a system whereby city appropriations might be made to maintain any proper relation to private contributions. He thought the trend throughout the United States was in the direction of municipal control. Mr. Folks was not at all sure if they did succeed in controlling these appropriations—a most desirable result in itself—that they would have freed themselves from some of the conditions that existed in Pennsylvania and Maryland, that was, that there was no longer log-rolling in our legislatures because the appropriations were made by the municipalities. But this should not drive them to the conclusion that the public hospital was in politics and the private one was not. With the gradual application of civil service laws and a higher standard of public opinion, the public hospitals had left behind them the greater part of the burden of politics. The private hospitals through their participation in city grants were finding themselves more and more entangled in a more dangerous form of political and sub-political activity. Mr. Folks said that it was not yet clear that a uniform standard of efficiency had been attained by the hospitals receiving city aid. If they could have the cooperation of the private hospitals in developing an adequate system composed partly of private and partly of public hospitals they should by all means have such a system. It was intolerable that private hospitals hoping to enlarge their work should be found opposing the establishment of new public hospitals, and themselves not occupying the field. If these were to remain a part of the great hospital system to which they all looked forward, they must join with Dr. Goldwater and others in urging the adequate development of both private and public hospitals, so that, fitted together, they would make an adequate and comprehensive system.

Dr. Frederic R. Sturgis said he was very much interested in the question of public appropriations to private institutions; as a general proposition he did not think it was quite proper to appropriate the public money to private purposes. It was a bad principle. The proper function of the city and municipality was to attend to the public health of the community; first, in efforts at the prevention of disease, if possible, and, secondly, to aid those who were sick to get well. It had always been observed that when the amount of public money went up, the amount of money from private sources went down. In his opinion it would be wise to have the city divided up into districts; in each district there should be one emergency hospital, and this hospital should care for none except in that district. Then for every two or three districts there should be one general hospital. He wished to emphasize his belief that the appropriation of public funds should be cut away from the private moneys.

Dr. Frank Van Fleet said that on receiving the notice of the meeting the title of the papers had suggested two thoughts to him: First, that history was repeating itself, and, secondly, that long ago it seemed as if the last word had been said on this subject. He recalled the fact that ten or more years ago certain of his colleagues had appeared before the Board of Estimate and Apportionment asking for appropriations to certain hospitals and had been characterized by certain other colleagues as "well

dressed medical mendicants." That was long ago, and in the interval public appropriations to private charities had not been contested, and it seemed as if the last word had been spoken. Evidently he was mistaken. It did not seem to Dr. Van Fleet a valid argument to urge as an objection to an admirable system in New York the conditions existing in Maryland and in Pennsylvania; if any argument was to be raised on this score, it should be that these two States should come up to the standard New York had created. He did not think they were called upon to answer the question propounded by Mr. Folks, what would have happened if these private charities had never been created? They had been created and they existed, and the conditions confronting them was not a theory but a fact. There were many reasons why the public funds should be appropriated for private charities. The people wanted them, and that was a very good reason. There was a very large class in the community whose salaries had not kept pace with the increased cost of necessities, and these people required the help hospitals could give them, for often they had not the money to pay for such help. As Dr. Goldwater had said, people preferred to go to private charities, and because of the demands made on them, private charities needed public help. Then again the city saved money by appropriating public funds to private charities. If the city paid to a hospital one dollar a day toward the care of a patient, and it cost two dollars or more a day to care for such a patient, the city saved the difference, for the hospitals in New York City by careful management had reduced such cost to the minimum. Another important point which had not been brought out was that the City of New York was a great center not only financially and commercially, but medically as well. Medical men came from all points to New York to learn the latest and newest methods for treating disease, and it was a distinct saving to the people of New York to provide the facilities for up-to-date teaching. Time did not permit him to go into further detail, but Dr. Van Fleet said he was sure that with the opportunity to present the subject many convincing reasons could be advanced why the City of New York should continue to appropriate public funds to private benevolences.

Dr. Henry G. Piffard said there was no escape from the conditions that existed in regard to the appropriation of public money to private institutions, but it seemed to him that when money was contributed there should be a string attached to it, which was not the case to-day. In other words, the city government should be represented on the board of hospital trustees in an equitable manner in proportion to the amount contributed by the city.

Elements of Success in Surgery.—Cordier concludes an article on this subject with the following deductions: 1. The field of surgery is a vast one, and is best covered by the specialist in some of its departments, the eye and ear especially. 2. Surgery and medicine should go hand in hand in the treatment of border-line cases, but should be divorced in the strictly surgical or medical cases. 3. The selection of a surgeon for a given case should be made from no other standpoint than that of his recognized ability. 4. A surgical operation should be performed as quickly as possible, consistent with good and completed technique. 5. All unnecessary and rough handling of important tissues should be avoided. 6. Careful, short anesthesias will help to keep the death-rate low. 7. Careful hemostasis with proper ligature material is an important element in successful surgery. 8. Thorough aseptic technique should be carried out, and may be obtained either with or without rubber gloves and mask. 9. Lawn tennis suits and gloves are only too often the avenue leading to wound infection. 10. Short post-graduate courses instill false surgical confidence, and lead to many surgical disasters. 11. Honesty and sincerity should ever be the keynote in deciding as to the advisability of performing any surgical operation. 12. Mental tranquility of the patient is of much importance preceding the performance of some surgical operations.—*The Lancet-Clinic.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of March 12, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	878	166
Diphtheria	423	44
Measles	1,544	33
Scarlet Fever	686	30
Smallpox	—	—
Varicella	218	—
Typhoid Fever	28	6
Whooping Cough	37	2
Cerebrospinal Meningitis	1	9
Malarial Fever	—	—
Totals	3,815	290

A New Pathognomonic Diagnostic Sign in Neoplastic Stenosis of the Colon.—C. Minerbe and D. De Giacomi, in a case of lymphosarcoma of the colon and retroperitoneal glands, demonstrated that the colon was obstructed by inflating the intenstine with a bicycle pump attached to an intestinal tube. The strong impulse which was imparted to the air in the colon by the stroke of the piston caused expansive pulsation in the tumor, which could be felt by the hand placed on the abdomen. He considers this a pathognomonic sign of obstruction of the descending colon. After a series of experiments on the cadaver and the living body, he states that the following conditions must be present to give a successful test by this method; they are an intact sphincter ani, and the presence of stenosis of a certain degree due to degeneration of the intestine. The walls of the colon must be indurated by infiltration, and not the entire circumference of the intestine have been invaded, so as to render it inextensible. Unfavorable conditions occur with thick abdominal walls, deep situation of the colon, fullness with feces, and contraction of the abdominal walls. The same method applied to the stomach with an esophageal tube causes the stomach to stand out, so that its boundaries may be seen through the abdominal walls.—*La Riforma Medica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 11, 1910:

		Cases.	Deaths
CHOLERA.			
India, Calcutta	Jan. 16–22	..	87

ON THE SENSE OF CONTACT AND THE GENESIS OF PLEASURE AND PAIN.*

BY EDWARD BENNET BRONSON, M.D.,

NEW YORK.

IN a paper read before this Society some twenty years ago, entitled "The Sensation of Itching,"† I sought to trace the origin of this so-called sensation to a disturbance of the primal sense of contact. The theme led the writer incidentally to make some excursions into the domain of general sensibility. Now, with still greater temerity, he attempts to trace from the same point of departure the origin of that manifestation of the affective life known as the feeling of pleasure or pain. Though pleasure and pain are states of consciousness, diametrically opposed to each other, they are correlative states, and the solution of one would seem necessarily to imply that of the other. The problem has always been baffling, and perhaps this very character is the lure that impels one, like the moth, to approach the light at the risk of singed wings.

In the solution of any problem, the most natural course is to try to reduce it to its simplest terms. The different characters or qualities of any product, however familiar with them we may be, by observation, are best understood and appreciated by tracing them back to their first beginnings. Is this not also true of the characters and manifestations of that most complex of all products—the living sentient organism? It is not by observation of its varied functions, faculties, and feelings in their state of high development that we should gain the fullest understanding of any one of them, but by tracing the thing back from the more complex to the more simple forms, and as far as possible toward its primal state. Even the study of mind, long the exclusive province of the psychologist, is coming more and more into the purview of the physiologist and biologist. In pathology, too, biogeny plays an important part. The tendency in disease to reversion to simpler types is a point of no little moment in this study, and applies to mental and nervous affections, as well as to diseases of the body generally.

Because of the complexity, the infinite variety of human feelings, it is better at first to reverse the route above indicated, in this particular excursion, and begin at their common starting point, and thence follow out synthetically their subsequent divergences and relations. That starting point we find in the sense of contact, a sense that still exists, and is identical with that primal sense that in the early forms of animal life enabled the first organized communication with the external world. Previous to this, external stimuli could have affected only such molecular and formative changes as pertain to vegetative growth. With the first intimation to the animal of a difference between one kind of contact and another, the way was opened to all the sensations, and we approach the threshhold of objective consciousness.

Through prolonged exercise of this primal sense, there were gradually evolved the special sense organs, not only those pertaining to the sense of touch (more properly called the sense of pselaphesia), but also the organs of sight, hearing, taste, and smell, and to these was added the muscular sense. Combined and coordinated, these organs constitute the means of intercourse with the outside world, the primary and essential source of all knowledge. This development presupposes, of course, long periods of progress. First, there were the æons on æons when progress alone depended on haphazard adaptation and selection. After this, with the appearance of the vertebrates, "the centralization of the nervous system," and the birth of consciousness, through purposive adaptation, the progress was enormously accelerated.

An elemental factor throughout this progressive development has been the principle of attraction and repulsion. Concerned at first only with nutrition, as development advanced it has remained a potential governing factor in every vital process. Under its influence, agreeable or agreeing external contacts tended to increase of nutrition and increase of vital power, disagreeing contacts led to impaired nutrition and deterioration of power.

Again, every contact effects a certain material change in the organism, and this change is more or less lasting, depending on the amount of beneficial or injurious effect. Such change is augmented by each repetition of the same contact or conditions of environment, till, through repeated similar experiences, fixed by heredity, there is finally acquired a sensitiveness to particular impressions. This retention of impressions is the basis of unconscious or conscious recollection, habit, instinct, and, with the advent of intellect, memory. By a similar process, there develops in consciousness a sense of the agreeable and disagreeable, of order and disorder, of fitness and unfitness.

These constitute the chief controlling principles of all development, and, so far as finite mind can penetrate, the final causes of evolution. Natural selection, essential as it has been, is only an accessory. The product in the development of man is a vast complex of movements, organs, functions, feelings, and, finally, intellect, whose activities, coordinated, make the cosmos of the living sentient being; incoordinated, tend to deterioration, dissolution, death. Every phase of these activities should be reducible to one or to some combination of the

*Read before the Section on Neurology and Psychiatry of the New York Academy of Medicine, Feb. 14, 1910.

†MEDICAL RECORD, New York, Oct. 18, 1890; Selected Monographs on Dermatology, London; The New Sydenham Society, 1893, p. 299.

above controlling principles. Is not such a reduction possible with regard to pleasure and pain? No definition or explanation of them can be satisfying that gives no intimation of their true origin and descent.

The teleologists would explain the existence of pain and pleasure as an essential part of the divine scheme of reward and punishment. There is a suggestion of truth in this, inasmuch as the development of these feelings has, perhaps more than that of any others, furthered the purpose of self-preservation. The burnt child dreads the fire. Repeated experiences of harm resulting from certain acts or encounters, tend to the formation of habits and instincts that contribute to the safety of the individual and of the species. Whether pleasure or pain has exercised the greater control, is doubtful. Sometimes the dread of pain would seem a more potent influence for good than is the prospect of pleasure. Indeed, we have often been led to believe that there is more of saving grace in the threatened terrors of hell than in the promised beatitudes of heaven.

Some distinction should be made between the feeling of pleasure or pain considered abstractly and those mixed states of feeling we know as pleasureable or painful. The quale-theory, so well expounded by Mr. Marshall,* is unquestionably true, so far as it goes; but the theory would seem to concern itself rather with what are pleasureable or painful states—that is with mixed states of which pleasure or pain is a part—than with the abstract conditions that underlie the latter. To define "pleasure-pain" as merely a quality, would seem to present this most important sense as merely of ancillary significance. It may be associated with any of the sensations, as it is with many emotions. It is true that while in sensations, and also—though to a less extent—in emotions, the element of objectivity predominates, there is in pain and in pleasure invariably and essentially an element of subjectivity. In the purest states of pleasure and pain, consciousness of the external world is supplanted by self-consciousness—an agreeable self-consciousness or a disagreeable self-consciousness—though, as a fact, pure states of pleasure or pain rarely, if ever, exist. Almost always there remains some trace of objective sense, even when the object is something pertaining to the ego itself, as in somatic pains or in pain attending an acute, local inflammation.

Between the pain or painful feelings associated with mental states, and what is commonly known as physical pain, there is an apparent disparity, but if the rationale of their production can be shown in both cases to be identical, the discrepancy disappears. The difficulty has arisen from the method of considering pain and pleasure only as concomitants of certain states of mind or feeling. But whatever pleasure or pain may be, abstractly considered, in all their manifestations the essence is the same, whether we call the feelings they alloy pleasurable and painful or agreeable and disagreeable.

The simplest disagreeable feeling, the simplest of all conscious disturbances in the skin, is the sensation of itching. The most rational explanation of this disturbance is found in referring it to that embryonic and but slightly differentiated sense—the sense of contact. There is good reason to believe that at the earliest stages of sentient life, neither pleasure nor pain exists. They presuppose a certain grade of development, a certain complexity of the nervous structure, which the primordial sense of contact must have anticipated by long ages. First, the sense of contact would acquire through experience and instinct the ability to discriminate between contacts that were congenial or uncongenial, agreeable or disagreeable. The first sentient effect of contact is to call attention. If the nature of the alarm is not recognized, the result is apprehension, the analogue of fear (the simplest, and by many, designated as the most primitive of all emotions). In itching, however provoked, there is always the representation in consciousness (or subconsciousness, if you will) of a foreign body in contact with the surface. It is that sensation that experience through many stages of animal life has taught is often followed by a prick or a sting, or some other miniature attack, and the inclination to escape the threatened hurt has grown into an animal instinct. The natural response is to repel the intruder, which, in itching, usually means to scratch. If the itching is not relieved, there ensues a nervous commotion with more and more strained attention until such time as the surcharge of disordered energy is released—until the tense attention is relaxed. In the operation of the higher tactile sense (pselaphesia) the nervous excitation is transmuted into a clear perceptive act, and there is no disagreeable nervous tension, no engorgement. In the one case, there is coordination; in the other, incoordination; in one a conscious equable adjustment of impressions received at the surface to the higher sensory organs; in the other, failure to connect with these organs produces conscious disorder.

In almost every case, at the start at least, itching may be instantly relieved if a strong and clearly defined impression, a perceptive impression, is made on the affected part, such as by firm pressure, by scratching, or by substituting a distinct sensation of another kind. Sometimes the temperature sense will do it, as when we evoke the sensation of cold by applying menthol; or the sensation of heat produced by hot applications. It is not so much substitutive irritation that produces the effect as the substitution of one sensation (if we may call itching a sensation) for another which is capable of coordination with higher nervous centers. In the feeling of itching, there is a content of vagueness and uncertainty, such that the sensation is incapable of interpretation.

This state of baffled and fretted nerves closely corresponds to the fret of mind when confused and misdirected thoughts are baffled in their decisions and judgments, "and enterprises of great pith and moment, with this regard, their currents turn awry and lose the name of action." Neither worry nor fear (to which we have already compared the sense of itching) could be called actual pain, and yet they illustrate its origin. Fear is not pain so long as a conscious power of resistance remains. Abject fear, terror, and extreme cowardice are relatively states of positive pain, because with them goes the consciousness of lost power of resistance. In fear, as also in regret, in proportion as the consciousness of effective action declines, there supervenes more and more an affective condition that is a painful one. When eventually these become terror or profound grief, the effective action has broken down, and there remains only a suffering self-consciousness. When the collapse extends, as it may, to the affective fac-

*Pleasure, Pain and Sensation, by Henry Rutgers Marshall, The Philosophical Review, Vol. 1, No. 6, p. 625.

ulties as well, the result is loss of all sensibility, and at the same time cessation of functional activity; such as occurs in shock and syncope. In physical pain, the essential conditions are practically the same, but in this kind of pain no intellectual or emotional process, nor any highly specialized sense being involved, it is much simpler in character and more rapidly developed. In itching, though the sense involved (the sense of contact) is not highly specialized, it suffices to give to consciousness strong objective impressions or representations as long as it lasts. Physical pain may suddenly supercede it, but the two feelings cannot coexist. Physical pain tends to that state of anesthesia in which specialized sense is annulled.

All the specialized senses are subject to disturbances corresponding more or less closely to itching of the skin, when it is only the primitive phase of the sense that is concerned. The effect of a flashing, and especially of a flickering light on the eyes, is one instance; that of confused and perturbing noises on the ear is another—the effect on some people of the din of the city, or on others of the babble and chatter of the afternoon tea. All imply vexed and fruitless attention. There is intrusion on the sensory equilibrium that finds no coordinate action to counterbalance it; the energy is there, without the directing sense—a fire alarm that doesn't tell where the fire is.

These disturbances are all concerned with special senses in their simplest or embryonic phases. The reactions to which they give rise are essentially instinctive and closely allied to unconscious reflex action. Indeed, they often occur independently of consciousness, as when one scratches an itching spot in sleep. The instinct is always a repulsive one, whether attended by consciousness or not, but when consciousness is added, something other than the factor of repulsion comes into play. We are not only cognizant of the act of repelling, but with this goes a sense of more or less effective energy. The more effective the energy, the greater the feeling of satisfaction. In its nature this sense is identical with what in higher activities we call the joy of combat. We are all more or less susceptible to the enticements of conflict, with its chances of advantage and hope of gain. In one and the same process may be associated the painful stress incident to a struggle and the pleasurable consciousness of effective energy.

But there is another sense phase in the active processes connected with disturbances of feeling that corresponds with the moment of relief. As the strained attention is relaxed, as the surcharge of energy is released there succeeds often a pleasureable feeling that is not the same thing as the agreeable consciousness of effective energy, nor of effectual energy only. It is the consciousness of a changing process with a sense of another kind of energy which is a reflection of the primary action or activity in a different medium. It is not the discharge of energy, nor is it simply the restoration of equilibrium; that would be merely rest, an unconscious state. In simple disturbances that is often the only sequel of the sensory process, but in greater disturbances the discharge of energy is not simply dissolved but is transmitted into other forms of nervous activity, conformably to the law of conservation of energy. What then produces the agreeable consciousness that attends the cessation of strained attention? It is not merely relative; it is not simply a sense of contrast, a sense of ease following actual discomfort, or the apprehension of discomfort. This means content, inertia, apathy—simply neutral states which connote equally absence of pleasure and absence of pain.

It is more or less generally conceded that an essential condition precedent to either pleasure or pain is one of hypernormal activity, but what becomes of the excess or why its dissipation when the acme is reached, should be accompanied with either pain or pleasure, is a question presenting difficulties. It has been said that when the excess goes to replenishment there is pleasure; when, on the other hand, it tends to harm, to deterioration, pain results. But how a state of replenishment, or of deterioration can *per se* be a conscious state, is not clear. It may be granted that with the replenished organism there is a consciousness of well being, but the feeling exists only by comparison with some previous condition of discomfort. When the pangs of hunger have been appeased, there succeeds such a sense of contentment, of well being, but it is usually more or less a sluggish, torpid feeling. It is not the state to which we would apply the name of positive pleasure. Positive pleasure occurred at the period of relief—a sense of gratification that concerned not appreciably the organs needing replenishment, but engaged activities of sensation and movement of great complexity. Chiefly affecting the special senses of taste and smell, the overflow of energy finds its sympathetic echo throughout the entire sensorium. In the paper on itching above referred to, it was said that "the very act of scratching appears to evoke a condition of erethism, and excitement far in excess of the mere pruritic irritation. The delight of a child in having its back scratched on removing the clothing at night is chiefly due to awakened sensations quite independent of the feeling of itching, and which are distinctly voluptuous in character. Then the scabious Scotchman at the scratching post fervently ejaculates his 'God bless the Duke of Argyle'; it is not only the negative satisfaction of relief that he feels, but a sense of positive enjoyment; he is having the pleasures of a gratified sense."

That pleasure does not consist merely in a sense of relief, but rather in action atending the relief, is illustrated also in the simple act of sneezing. The desire to sneeze begins with an irritation of the Schneiderian membrane, with the inclination to dislodge an offending body. It corresponds to the itching of the common integument, as the act of blowing the nose corresponds to the act of scratching in pruritus. If blowing the nose does not relieve the irritation, there ensues a series of movements, partly voluntary, chiefly involuntary, the issue of which is that convulsive explosive effort, the sneeze. But if after the first preliminary movements the explosion fails to occur, even though the original irritation has disappeared, how common for the subject to exclaim: "Ah! I missed that," and with a tone of positive regret. A similar instance is where pleasurable feelings are excited in pruritus of the external auditory meatus, by introducing the tip of the finger and making rapid vibratory movements. There are many other instances of like character. That the conditions described are exactly paralleled in the orgasm of aphrodisiac sense, which represents the acme of physical pleasure, is sufficiently obvious, without more particular comment.

One of the commonest manifestations of pleasure is laughter. In this, there are conjoined activities of mind with others of a lower rank. First, there is evoked in the mind, usually after a certain more or less prolonged fixity of attention, a concept, that, owing to its absurd or unexpected character, finds no ready solvent for the awakened interest and energy in its appeal to reason; the capacity to receive it is not there, and the result is an overflow into lower channels of physical action. For relief, as in the case of itching, there is involuntary recourse to muscular action, with more or less convulsive, sometimes rhythmical movements, of the facial, respiratory, and vocal muscles, and sometimes, in the transports of hilarity, extending over the entire organism including even the organs of secretion. The incitements to laughter are most irresistible when the mind is taken most unawares. But the personal equation plays an important part. To one, a witticism will evoke only a smile, because it directly evokes a train of coordinate ideas that afford adequate capacity for any excess and overflow of mental energy; to another, who is able merely to grasp the absurdity, no such outlet presents itself, and a burst of laughter is the only recourse. Yet though the simple minded laugh easiest, it is by no means merely a question of mentality. It is rather a question of individual organization. Some organisms by nature seem specially attuned to sensations of pleasure; their nerves vibrate and thrill in response to agreeable stimuli, in sympathetic chords, like the overtones of music; for them is

> ".....the goddess fair and free
> "In heaven yclept Euphrosyne,
> "And by men heart-easing mirth."

Some take their pleasures more seriously and such need be neither hypochondriac nor bilious. To them Milton's

> ".....goddess fair and holy
> ".....divinest Melancholy"

is "the Cherub Contemplation."—But however we take our pleasures, whatever be their sources, and whatever their manifestations, their rationale remains the same—the release of surplus energy in coordinate and coordinated activities.

The effect of personal equation is seen also in the fact that the same stimuli that cause one confusion, distress, and pain, such as the *sturm und drang* of town life, the passing with sound and fury of a fire engine, an express train rushing by, may to another give only a stimulating and sympathetic impression of coefficient energy. The grandeur of a tempest, that to one strikes only terror, to another is rather an "ennobling stir" in which he feels himself "exalted." To him it is a grand fortissimo of nature's harmonics, and it affects in him a sympathetic emotion not unlike that produced by the fortissimo of an orchestra.

The personal affect produced by music varies greatly according to the individual's susceptibilities. Every one has a sense for rhythm, whether in the flowing measures of verse, or of prose, of the dance, or of music—and even for certain rhythmic motions of inanimate nature.

The pleasures of music are both emotional and intellectual. While the latter are reserved for the connoisseur, including as they do the more abstruse matters of form, balance, theme, counterpoint, orchestration, and the like; the capacity for emotional response is more universal. Though "the man who hath no music in himself" is a rare anomaly, in many the coordinate affect is too slight to control sustained attention. The effort of attention becomes simply a derangement and disturbance of sense, for which the relief usually sought is to do something or to say something, unconscious of the disarrangement of senses in the rapt listener near by, on whom it acts like those particular interferences or "beats" in musical notes, whose effect is always dissonant and disturbing. To some, it is the so-called "program" character that chiefly appeals; but usually it is not so much that it presents to imagination any particular things, as that it arouses particular emotions. To enjoy this, it is necessary to be in a state of sympathy. In the contemplation of any work of art, if we are conscious of an idealized intention expressed in truthful form, even though the emotion or the ideas aroused in the listener or observer may differ from what the artist had in mind, the response is a coordinated one, and provides a sufficient capacity for the attention evoked, and the effect is pleasurable.

With regard to the pleasures or pains of memory, the same principles obtain as in other feelings, but here may be noted a marked difference between pains or pleasures that are intellectual and those that are purely sensuous. We can recall in memory a pleasurable or a painful experience, but we can only recall the fact of a physical process. A sensation once felt cannot be repeated in consciousness without the physical conditions that originally produced it. In hysteria or melancholia, or in allied conditions, there may, by autosuggestion, be imaginary physical pleasures or pains, but they form no part of normal sensibility. In grief, all the circumstances attending the loss may be repeated in consciousness through memory, together with the affections that were blighted, and again, as originally, they vainly seek an outflow; their object is irretrievably gone, and no capacity of mind or feeling is capable of receiving them. All the reawakened energies of the original attachment are there, but without the accustomed outlet they rebound on the disturbed sensorium, like waves dashed on a barren and rocky shore.

Mathematically stated, pleasure and pain might be termed the coefficients of effective and of ineffective energy. But they are also conscious states; either it is conscious adaptation or conscious ineptitude. For they are always more or less egotistic states. In their higher manifestations there is increasing detachment of the ego from the non-ego; the sense of effect is supplanted by a sense of affect; it is either self-consciousness elated or self-consciousness abased. In the highest of these states self-consciousness becomes supreme. In the extremity of pain the struggle for existence ceases to be an object and gives place to an agony of despair. At the supreme heights of pleasure all objective sense is merged in a sense of transcendent capacity. It is the supreme exaltation of self. In the ecstasy of adoration the subject sits with his god.

To whatever heights these senses ascend, or whatever depths they sound, as in every manifestation of sensibility of which man is capable, it all harks back through the mazes of evolution to one common and simple progenitor—the sense of contact, and to efficient causes that lie in the elemental laws governing the universe.

10 West Forty-ninth Street.

THE DIAGNOSIS AND TREATMENT OF INTESTINAL PROTEIN INDIGESTION.

By A. E. THAYER, M.D.,
AND
RAYMOND C. TURCK, M.D.,
JACKSONVILLE, FLORIDA.

Dyspeptics may be divided into those who have gastric and those who have intestinal dyspepsia. The latter group includes those who are unable to digest proteins and those whose metabolism of carbohydrates or fats is imperfect. Protein intestinal indigestion, however, is so common that autointoxication, intestinal intoxication, intestinal dyspepsia, and similar terms are generally understood to refer to it alone. Proteins in the diet not only have the disadvantage of producing more waste material than the carbohydrates, but also are peculiar in that they undergo, if not promptly and perfectly digested, a true putrefaction in the intestinal canal. The products of this putrefaction are numerous and of varying toxicity, but apparently the most important, and clinically the most easily recognized, are those connected with the aromatic group in the protein molecule; their common substance of origin is tryptophan.

Since Tiedemann and Gmelin, in 1831,[1] first showed that tryptophan is one of the substances split off from the protein molecule in the process of digestion, the further studies of Nencki,[2] Ellinger and Gentzen, [3] Hopkins and Cole,[4] and others have established its importance as a precursor of indol and of urinary indican, and, for the practical physician, the recognition in the urine of indican and similar derivatives of protein decomposition will help to make clear the underlying fault in many a puzzling case of deranged metabolism. Urinary indican, or indoxyl-potassium sulphate, and the accompanying skatoxyl-potassium sulphate, which usually exceeds it in quantity, may be interpreted as themselves the cause of the clinical symptoms or as merely the indications of deeper causes. They take their origin in the protein molecule of animal protein in the diet, but vegetable protein may, and the body's own intrinsic proteins in some cases certainly do, furnish them in pathological conditions; and it is noteworthy that proteins which are poor in aromatic radicles are but little subject to putrefaction in the intestines and do not furnish these products to the urine. Part of the indol, or benzopyrrol, formed in the gut remains in the feces, while part is carried to the liver in the blood of the portal vein, and in that organ it is combined with oxygen to form indoxyl, which then unites with potassium sulphate to form indoxyl-potassium sulphate, the "indican" excreted by the kidneys. The skatol goes through a similar absorption, oxidation, and excretion, a part remaining in the feces. The other end-products, phenol, volatile fatty acids, gases, etc., are passed with the feces; hence the indican and indolacetic acid voided with the urine have a valuable significance and should be tested for in every examination. If this is not done a threatening toxemia may not be averted, or, if already existing, it may be overlooked.

The clinical expressions which may be due to protein indigestion are manifold, and it may safely be claimed that any of the great systems of the body may be deranged from such faulty metabolism, this feature being common to all, that for a time, often for a very long time, the trouble is functional, but at any time structural changes may be added. Generally the illness is of mild type and of annoying character, but the symptoms may be sudden and severe, as in Taylor's case[5] of heart block due to intestinal toxemia. In this case there was a radial pulse of 28, a pulse in the jugulars of 96-98, with urine of high specific gravity (1,033) with much indican; the entire group of symptoms yielded to treatment of the intestinal condition. The author cites a similar case of Babcock's.

Patients with protein enterotoxemia are frequently treated for long periods for anemia, headache, neurasthenia, disease of the skin, the liver, or the kidneys, or for "dyspepsia" of undefined type, with but transient if any relief, and frequently drift from one physician to another in habitual invalidism. Almost without exception they are self medicators, repeatedly prescribing cathartics and other drugs for themselves, for experience has shown them that a brisk purge gives relief for a day or two. A patient may be apparently in good condition, with no marked loss of weight, or pallor, and may have a fair appetite; or there may be severe anemia, marked decrease in weight, headache, lassitude, mental weariness, insomnia, melancholy, constipation, scanty urine, and albuminuria. As a rule, the history covers periods of months or even years, and often includes an unwise use of proteins in the diet. Patients are frequently encountered who eat meat three times a day, often with cheese, eggs, leguminous vegetables, and milk at the same meal, or, on the other hand, there may be a history of but little protein excess in the diet; and this would mislead us unless we realize that the underlying condition is not so much due to the number of grams of meat ingested as the inability to digest any; in such a state a few grams of protein may be enough to form poisons that will cause severe symptoms. Here it is well to remember that the dosage of these poisons may be infinitesimal, but potent because of constant repetition. Herter[6] caused indolaceturia in two persons, who had not suffered from it before, by increasing the meat in their diet.

Protein toxemia may manifest itself chiefly as anemia. Grawitz[7] recognized the close relationship of pernicious anemia and autogenous poisons. To this view Ziegler apparently subscribes,[8] and undoubtedly many of the chloro-anemias of young girls have this origin. In other cases the nervous system suffers most; but few cases are entirely free from nervous symptoms; and while in one case there may be only headaches and ill-defined fears, in others there is profound neurasthenia, or such melancholy and self-distrust that business is impossible, too often the patient going on to actual mental disease. In each type, until the intestinal condition is recognized and treated, nothing can be done for the nervous disorders. Durand[9] describes a case of tetany from such autointoxication, and the psychic phenomena are well given by de Vries.[10]

The relations between diseases of the eyes and intestinal toxemia are presented by de Schweinitz and Fife,[11] and in the discussion on their paper.

Cases of protein enterotoxemia are more common among adults, but they may also be found among infants. Longo's studies[12] on protein metabolism among infants showed that the toxicity of the urine is least on vegetable diet, but it increases on milk diet, is higher with meat, and highest with eggs, while the evidences of intestinal putrefaction increase in the same order. Herter[13] points out that imperfect development of the skeleton and similar metabolic faults may be closely related to the intestinal flora in infants.

As to the confusion between these cases and nephritis, it should be remembered with Neumann[14] that not every albuminuria indicates a true nephritis, for albumin and casts may be merely the record of renal irritation from elimination of toxic material formed in the intestines, which disappear on proper diet and treatment; yet it is equally important to recognize that long continued excretion of such toxic material will produce structural kidney lesions which may never go through the stage of acute nephritis.

In still other cases the main expression of the disease is some form of cutaneous eruption, as was observed lately by one of us (A. E. T.) in a case of universal pustular dermatitis herpetiformis, which had gone the rounds without relief until thorough examination of the blood, feces, and urine revealed the nature of the trouble. Many eczemas, etc., apparently due to external irritation, rest upon such underlying conditions, and are worse after every slight error in diet. As to the cases called dyspepsia, they are without number, and their true nature is not always recognized because every method for the examination of blood, feces, urine, and stomach contents is not exhausted, and hence, their treatment not being rational, improvement is but temporary if secured at all.

It is very important to observe that this condition of protein enterotoxemia is almost without exception secondary to some other condition. Its protean clinical expression shows that it is a clinical entity only in the sense that it persists for years, the site of absorption is in the intestine, and the patients may be separated into certain groups which have the causation in common. Some cases occur in diabetics who are on an exclusively protein diet, others in phthisical patients on forced feeding, but such cases are not considered here. Anders[15] separates cases which are primary and those which are secondary, but, in a strict sense, practically all cases are secondary, due to causes situated higher up. From imperfect mastication, insalivation, and gastric digestion, the food may leave the stomach all ready to putrefy, and the composition of the food may be of importance here, Tobler having shown[16] that a large amount of fat in milk delays its expulsion from the stomach, while addition of carbohydrates seems to hasten it. Zuelzer[17] has isolated a hormon from the stomach walls which caused increased peristalsis when injected intravenously. If we may assume that the presence of this is essential, and its absence causes food to stay too long in the intestine, some of the simpler cases may be explained as due to anomalous gastric function. Similar delay in the movement of the intestinal contents occurs with gastroptosis and enteroptosis, others appear to be reflex from chronic appendicitis and similar conditions. Some degree of ptosis of the transverse colon is very common, and this may be sufficient to produce slow peristalsis and absorption of the indol and skatol which are always present. In such mechanical conditions the element of the time required for the intestinal contents to traverse the length of the canal is very important.

In many cases the original fault is in the pancreatic function, and this may be recognized by the methods of Cammidge,[18] Schmidt,[19] the plate method of Schlecht,[20] and others. Probably pancreatic faults are among the most common, but with these or alone the liver's functions may also be deranged. Rodella[21] has recently shown that where too little bile enters the intestine there is a great increase in the Gram-positive bacteria there.

Frequently beside the overeating and imperfect digestion of proteins, there is abnormal innervation, which may follow the longer arc and cause headache, etc., or follow shorter arcs and derange the abdominal viscera in their digestive, internal secretory and blood forming functions, so that a double vicious circle is possible, and a similar explanation suggests itself for some postoperative temperatures.

Since these features are more or less distinct in nearly every case of the disease, it follows that, if the tedious and trying conditions are to be relieved, not merely the evidences of putrefaction are to be sought in the urine, but also the underlying and original cause must be found, and this implies exhausting the methods of examination of blood, urine, feces, and stomach contents, as well as a careful physical examination. Such patients are well accustomed to having the doctor glance at them and write a prescription, and usually welcome the explanation that thorough examinations of everything examinable are first necessary before either diagnosis or treatment can be considered.

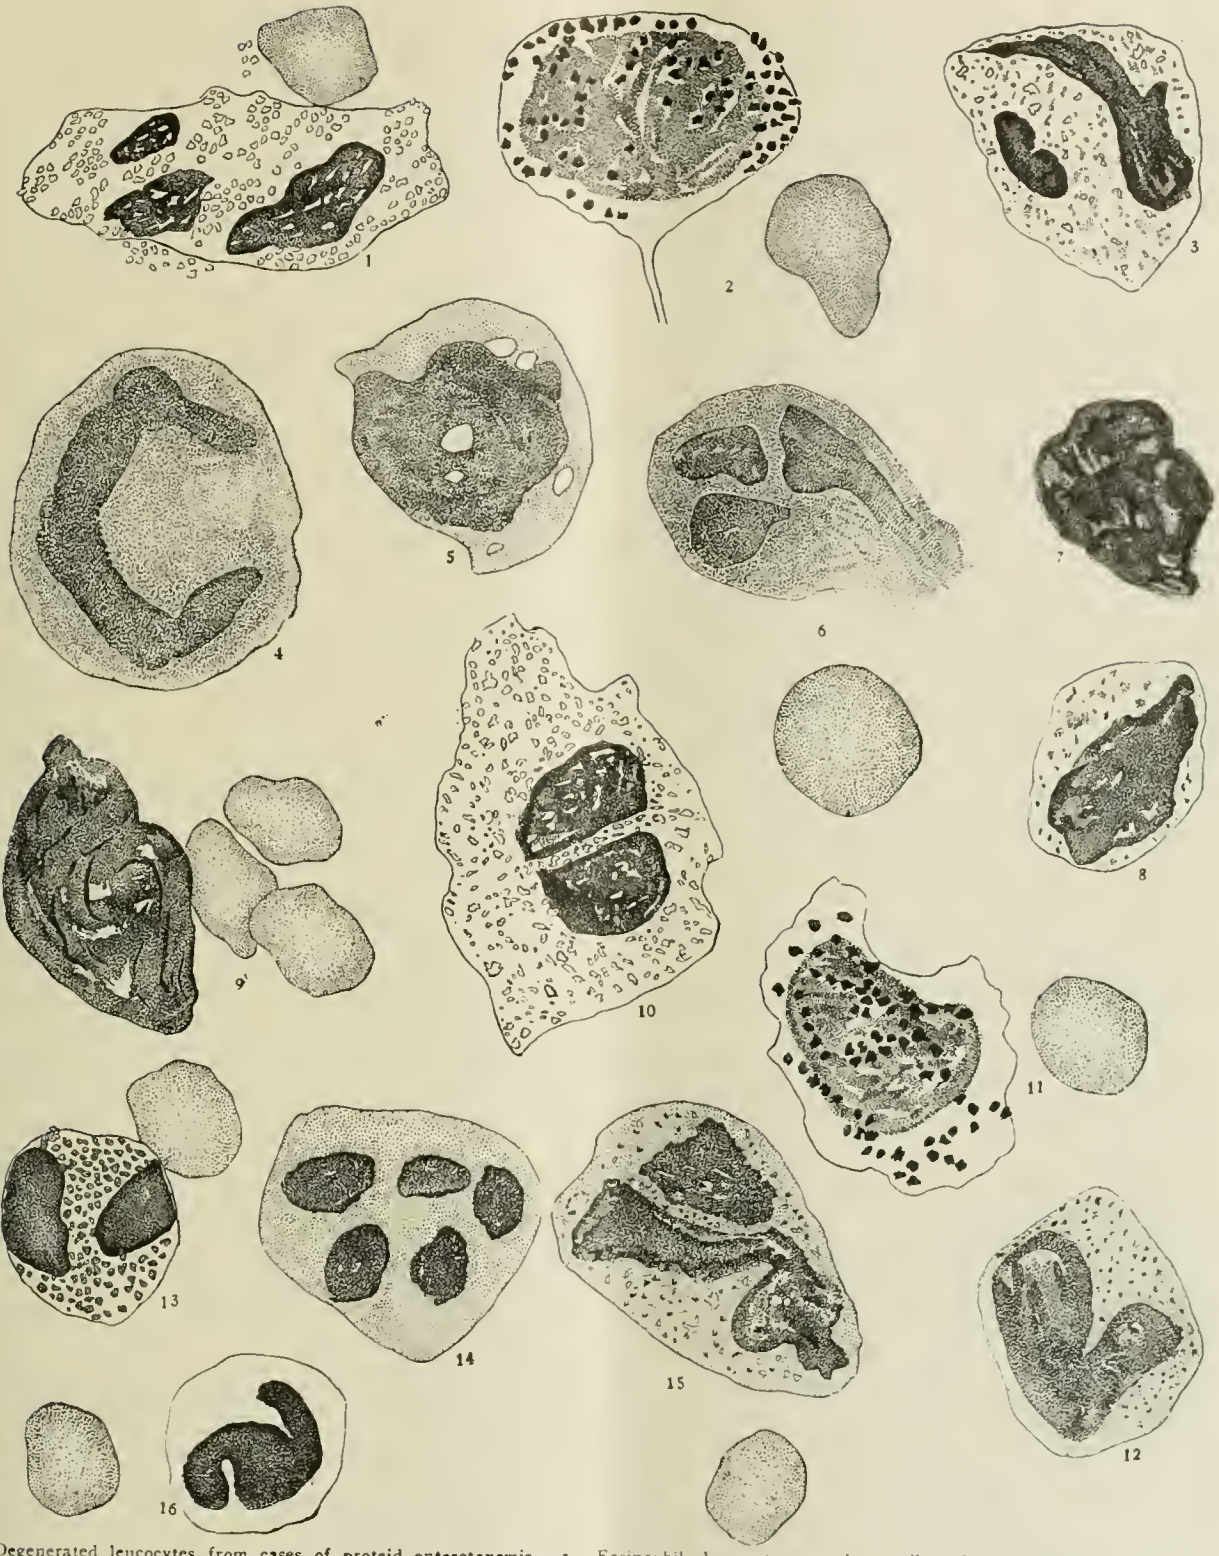
In describing the diagnostic methods no attempt will be made to exhaust the subject, but only those will be mentioned which any practitioner can carry out, and which have proved of value in our hands; others may be found in laboratory guides and recent periodical literature.

Urine. Besides the usual tests there are two of especial importance, namely, those for indican and for indolacetic acid. Indol is formed from the tryptophan which is early split off in digestion from the aromatic radicles of the protein molecules, and is oxidized and combined with potassium sulphate in the liver. The process may be expressed as follows:

$$C_6H_4\begin{matrix}\diagup CH \\ \diagdown NH\end{matrix}\!\!\diagup CH + O = C_6H_4\begin{matrix}\diagup COH \\ \diagdown NH\end{matrix}\!\!\diagup CH$$

and this, plus K_2SO_4, equals $C_6H_4.NH.CHKSO_4$, which is the ethereal sulphate called indican. In the urine it may be recognized by several tests. (a) Obermeyer's reagent consists of hydrochloric acid (sp. gr. 1.2) with 0.3 per cent. of ferric chloride: from 2 to 5 c.c. of this with an equal amount of urine and 2 c.c. of chloroform, are well shaken together in a test tube and allowed to stand, the chloroform settles out as a blue bottom layer; if ether is used it goes to the top as a blue layer, but it is liable to evaporate. This test has the advantage of affecting nothing but the indican and of removing most of it, but repeated shakings may be needed. (b) Hydrochloric acid with a trace of potassium chlorate gives a blue reaction. (c) Five c.c. urine with 3 c.c. saturated sodium perborate and 2 c.c. chloroform gives a blue color on shaking. (d) The permanganate test given by Porter[22] has not proved so good as the others in our experience. (e) The test for indolacetic acid will often show indican as well. Before testing for indican it is well to remove pigments and phosphates by adding to the urine one-fifth volume of 20 per cent. lead acetate and filtering.

The presence of indican in the urine is never normal, for it points to the putrefaction of protein material, either in exudates or necrotic parts of the tissues or in the alimentary canal; it usually stands in reciprocal relation to the indolacetic acid, and either may be abundantly present while the



Degenerated leucocytes from cases of proteid enterotoxemia. 1.—Eosinophile leucocyte, granules small, gathered in groups, some escaping, nuclei retiform and fragmented. 10.—Eosinophile, granules small, cytoplasm hydropic, nuclei dense and retiform. 13.—Eosinophile, of normal size, but granules deeply basophile. 2, 11.—Mast cells, one with projecting pseudopod, few scattered granules, nuclei swollen and pale with coarse retiform structure. 3.—Polynuclear, granules partly acidophile, nuclei dense. 15.—Polynuclear, hydropic, some granules acidophile, nuclei pale and hydropic. 4.—Polynuclear, hydropic cytoplasm without granules, deeply tinged by chromatin dissolved out of nucleus. 5, 6.—Polynuclears in the same condition with well-marked vacuoles in both cytoplasm and nuclei in 5, while in 6 the softened cell, deeply tinged with dissolved chromatin from its own nucleus, has evidently burst on spreading. 14.—Polynuclear, hydropic, tinged by karyolysis, nuclei pale and fragmented. 16.—Polynuclear, free from granules, pyknotic nucleus. 8, 12.—Large lymphocytes, swollen, cytoplasm granular with basophilic dots, nucleus deficient in chromatin. 7.—Free nucleus of large lymphocyte. 9.—Free and hydropic nucleus of large lymphocyte, the intranuclear torsion, as of an arrested spasm of the karyoplasm, well shown. Normal red cells drawn on the same scale for comparison. Drawn with 1/12 oil immersion, 3 eyepiece, Abbe camera, A.E.T.

other is reduced to a mere trace. One of us has a case of severe chronic neuritis, paroxysmal as these cases usually are, in which the indolacetic acid alone is found. Herter (loc. cit.) suggests that as indolacetic acid is not paired, like indol, phenol, and skatol, it may act directly on the nerves.

Indolacetic acid also is derived from tryptophan and all obstacles to the intestinal flow favor its formation and absorption. In its formation probably the *Bac. coli communis* and *Bac. bifidus* are concerned. It was described in 1882 by Nencki[23] under the name of urorosein. It may be detected in the urine by adding a few drops of 0.1-0.2 per cent. potassium nitrite solution and hydrochloric

acid (sp. gr. 1.2), the urine floated upon this shows a ring at the line of meeting which is pink, rosy red, or deep red. As Herter has shown[24] in his able paper on indolaceturia, some urines give the reaction upon the simple addition of hydrochloric acid, because nitrates are already present in them or form on standing, hence, when the test fails, nitrites must be added before indolacetic acid is assumed to be absent. With 1 per cent. calcium chloride solution instead of the nitrite the color is purple instead of red. When the urine contains much indican, this must be removed by filtering it, shaking with lead acetate, and employing the Obermeyer test. The urine above the chloroform may be removed by pipette and may then give a distinct indolacetic acid reaction. Another test for this substance is the addition of one drop of nitric acid to 2 c.c. of hydrochloric acid, floating the urine carefully on this as before. This urorosein reaction, for so long a mere curiosity, is shown to be of great importance clinically and should always be tested for.

It is convenient to note at least three grades of reactions for indican, slight, moderate, and strong, and this is sufficient for clinical needs, but a more elaborate indican scale has been devised by Folin. Brunon and Guerber[25] suggested a year ago that the proportion between the ethereal sulphates and the total nitrogen of the urine is an indication of the degree of putrefaction in the alimentary canal. Calling the sulphates A and the nitrogen N, the quotient $\frac{A}{N}$ which is usually 1.0 or 1.4, may rise to 3.0 with much protein putrefaction, or, in very severe cases, as high as 6.0 and 7.0, decreasing as the case improves.

By Cammidge's test[18] the urine gives an indication of the condition of the pancreas, based upon the occurrence of glycerin in the urine with destructive lesions of that organ; on heating with nitric acid or hydrochloric acid, glycurone is formed, which precipitates with phenylhydrazin as crystalline rosettes. The integrity of the hepatic functions may be studied in the urine by giving the patient 100 grams of levulose and then testing for glycosuria; if none is found, hepatic function in this respect, and presumably in others as well, is considered normal, but in the aged we may have glycosuria without actual liver disease.

Some of these cases have serum albumin in the urine, as a result of local irritation in the excreting organ. Others may show the presence of nucleoalbumin, which is easily recognized by the following test (Thayer's): Onto 5 c.c. of filtered urine 1 c.c. of 10 per cent. trichloracetic acid in absolute alcohol is floated; a pronounced white ring is formed at the line of contact, which the addition of glacial acetic acid dissolves. The source of this nucleoalbumin may be leucocytes from either the kidney, the bladder, or the vagina, especially when there is some complication like prostatitis or vaginitis, but in many cases the reaction is obtained when the microscope discovers few or no leucocytes after centrifuging. The exact significance of the test is not yet determined, but perhaps there is an increased discharge of mucin from the urinary channels similar to the catarrhal condition of the alimentary tract.

Blood. Smears are made in the usual manner and stained with Wright's stain, but frequently it is well to reinforce this with hematein for about three minutes, after washing off the former solution, following it by a dash of eosin, examining the dried preparation by the twelfth immersion lens. Very often there is but little decrease in the hemoglobin and but little variation in the distribution of it or in the size of the red cells, though with severe cases poikilocytes are very frequent. The pathological changes appear to affect leucocytes chiefly, and often but one variety of these, or one more than any other. In making a differential leucocyte count, few departures from the normal percentages may be observed, or the lymphocytes may be in excess with a high eosinophile count. Tanaka[26] notes an increase in the lymphocytes and the plates in neurasthenia in Japan and ascribes it to vasomotor influences. Rous[27] observed that the largest proportion of lymphocytes reach the blood stream by way of the thoracic duct, hence it is not surprising that irritation in the territory of its origin should raise the proportion of lymphocytes, and also cause degenerations of some of them before they reach the blood, and since eosinophilic leucocytes are normally present in the walls of the alimentary tract in great numbers, they may find their way to the blood along the same path.

Degeneration of the leucocytes in the flowing blood is only to a slight extent an expression of the old age of individual cells, their graveyard is elsewhere. When many leucocytes are degenerated it is safe to assume the presence of some toxic agent though it is not clear whether it acted before or after reaching the blood stream. Cadaverin, putrescein, and other toxic substances were found in the blood of pernicious anemia by Hunter,[28] and it may be these poisons or the ethereal sulphates circulating with the blood, which destroy the leucocytes. This is extremely difficult to prove, but the origin of such toxic agents is almost without doubt in the food passing through the alimentary canal, as is shown by their increase upon adding meat to the diet and their decrease on withholding it or supplying proteolytic ferments, with an accompanying change in the per cent. of degenerated leucocytes. The resistance of the cell and the intensity and duration of the toxic influence, doubtless control the number and kinds of leucocytes which degenerate; commonly the large lymphocytes and the polynuclears are the most affected, and it may be fair to assume that they are most sensitive to such destructive substances. Arneth claims that with infection the older polynuclears are destroyed first, which leads to a relative increase of younger forms, namely those with one nucleus, variously lobed. When abnormal cells occur, as myelocytes, they also may show degenerative changes. Hence in making a differential count, a separate notation of degenerated white cells and their kind should always be made, and later records compared with this will show whether improvement is taking place. Botkin's experiments[29] showed that different leucocytes vary in their resistance to noxious influences, and the same thing is shown clinically in cases of protein enterotoxemia, a rough scale of the frequence with which the cells degenerate being polynuclears, large lymphocytes, mast cells, and eosinophiles, and, most resistant, small lymphocytes. This tends to throw doubt upon the recent claim of Lefas[30] that the baso, ampho, neutro, and acidophile leucocytes are four stages of one and the same granulation, the acidophile being the oldest, for in that case there would not in all probability be such a variation in the resistance of these cells.

The degenerative changes, apparently, do not differ in kind from those observed in acute diseases and the essential anemias. They affect both the cytoplasm and the nucleus, usually both at the same time, but not necessarily to the same degree, the nucleus being more resistant. Affecting the cytoplasm, we find swelling by imbibition of fluid, up to complete solution or bursting, loss of granules as observed by Arneth and others, changes in the staining affinities of the granules so that some or all of those in a polynuclear cell may be red and those in an eosinophile may be blue, formation of vacuoles and pseudopods, separation of parts of the cytoplasm, and complete loss of it, as is common in the large lymphocytes. The nucleus may be pyknotic or hydropic, some of the larger look as if the karyoplasm were twisted and torn apart in places, arrested in an intranuclear convulsion, and in others this apparently has led to fragmentation of the nucleus, in some there are distinct vacuoles, in others the nucleus is a coarse net work. Frequently the fluid imbibed has dissolved the chromatin out of the nucleus and stained the cytoplasm, which is usually darker close to the nucleus and lighter farther out. Other nuclei, mostly of large lymphocytes, are naked, and may be of very irregular contour, budded and basket like. Some of the injuries noted are due to mechanical pressure while spreading the softened and swollen cells.

Digestion normally has some effect upon the blood, the outpour of the digestive fluids, about 1800 c.c. in all, tending to increase the proportion of cells and slightly raise the specific gravity, though a diet rich in fluids may have the opposite effect. Purging, either from medicine or disease, has a marked effect, causing relative increase of both reds and whites, greater specific gravity, and probably increased viscosity, and these effects are probably all more marked in the blood of the portal system than in the peripheral blood; this gives the liver an abnormal blood to work with and tends to produce thickened viscous bile. Since patients of this class habitually abuse salines we should consider whether we desire such effects and caution the patients accordingly.

While there is nothing pathognomonic about the blood, yet thorough examination should not be neglected, for certain characteristics, taken together with those of the urine and the feces, are found so commonly that they serve both to confirm the diagnosis and to measure the progress of the case; these include hemoglobin but little diminished, comparatively minor changes in the reds, at times poikilocytes, very seldom myelocytes or nucleated red cells, and with this uncharacteristic picture a notable proportion of degenerated white cells, often with increase of both mast cells and eosinophiles. These findings separate the blood picture from that of any essential anemia as well as from conditions where leucocytosis is an important feature. As improvement occurs the proportion of degenerated cells falls and the hemoglobin increases.

Feces. Both chemical and microscopic examination of the feces should be made, at least once, when the case is first seen. A specimen record of an actual case may serve to show the range of such an examination.

Miss B. Examination of feces, June 20, 1909; consistence, soft, reddish, gaseous, subacid; fat, present as such; protein, present by nitric acid, Esbach's test, and the ferrocyanide test; carbohydrates, sugar, starch, and erythrodextrin absent; occult blood, absent; lactic acid, absent; bile derivatives, much pigment present, some stercobilin; indolacetic acid, marked reaction; microscopic, much undigested muscle fiber, its nuclei lacking, oxalate of lime, few white cells, no reds, no fatty acid crystals, no parasites or eggs.

Such an examination is enough to confirm the diagnosis, explain the conditions, and serve as a basis for treatment. But there are other examinations of the feces which have for their purpose the recognition of the functional activities of the great glands and a few of these may be mentioned.

When protein is found in the feces, the question is still unanswered whether this is derived from the food or from the patient's blood by exudation, transudation, or actual hemorrhage. In the latter case the search for occult blood, and microscopic recognition of red cells, with other evidences of inflammation, such as pus cells and desquamated epithelia, and the presence of corresponding symptoms, will help to clear up the condition. Tsuchiya[31] has lately given a method of testing for certain proteins in the feces, after the latter have been freed from hydrobilirubin and nucleoprotein, as follows: 5 gms. of feces is rubbed up with water till thin, and the reaction is tested; 10 c.c. of this is rubbed up with enough 10 per cent. acetic acid, in a mortar, till strongly acid; then 5 c.c. chloroform are added and the mixture again rubbed up in the mortar; the entire amount is poured into a precipitating glass and allowed to settle, after which the upper portion, slightly turbid and yellowish, is removed by a pipette, and a disc of agar, which has been soaked in copper sulphate solution and dried, is put in it for an hour; the disk is then removed, placed on a white porcelain dish, and caustic soda or potash solution added; if there has been dissolved protein in the feces a distinct biuret reaction takes place.

The author never found this biuret reaction in normal feces, only once in 23 cases of intestinal dyspepsia, but regularly in all cases of diarrhea from intestinal disease and after purges which irritate the intestinal wall (calomel). With this simple method, if experience proves it reliable, an inflammatory factor may be recognized or excluded.

Schlecht[32] proposes a method for the recognition of trypsin in the feces which has the merit of gauging the digestive power of the ferment, and, incidentally, the functional activity of the pancreas. The patient's colon is cleansed by enema, with or without glycerin, a test meal of 150 grams of meat with the same amount of potato is eaten, after an hour a brisk cathartic is taken (calomel 0.2), which produces a thin stool in two or three hours. A portion of this is made alkaline and rubbed up in a mortar, and dilutions made with 10 per cent. glycerin water in the proportion of 1 : 2, 1 : 3, 1 : 5, and so on as high as it is desired to carry it; each dilution, after stirring, is used for planting on a serum plate, made with beef serum and dextrin broth. One plate may be used for all the dilutions of a single case by dividing the plate into sectors. The plate is kept for 24 hours at 37° C. and then examined for evidences of digestion, as little funnel shaped depressions where the trypsin has acted; the dilution at which these fail to appear gives the measure of pancreatic function. Where there is no disease of the pancreas there is usually a distinct dimpling of the plate with a dilution of 1 : 200. This test, in conjunction with Cammidge's test in the urine and the microscopic findings in the feces, will show the integrity of the pancreas.

The function of the pancreas may be tested by sewing a small piece of fresh beef in a circular piece of gauze and giving this with the food; when recovered from the feces only fibrous tissue should remain; if striated muscle fibers are still present and the fibrous tissue is but little affected the gastric function is imperfect, but if the nuclei are present in the muscle fiber the pancreas is at fault; if the muscle fibers are not stained with bile there is probably a deficiency of this fluid.

Loss of amylolytic power in the stomach may be tested by an Ewald breakfast, removed after an hour and a half, and this is important for many cases of protein enterotoxemia are primary in the stomach, progressing to loss of weight, constipation, and intestinal catarrh in consequence of the gastric insufficiency, and conditions are thus provided for protein putrefaction in addition. By giving dry meals and insisting upon thorough mastication the stomach condition can be improved to the benefit of the intestinal[33].

Histories. The following brief histories are fairly typical and are given more to show the condition of the blood, etc., at the time of beginning treatment than because they are unusual:

Case I.—Mrs. W., 45, married, has a history of chronic headaches and nervousness, voluntary emesis after meals from the fear that she might feel distress in the stomach, loss of appetite and weight. Her present weight is 115 pounds, has visited many springs and sanatoria, is continually reading popular medical works and treating her own case, is full of fears and almost desperate. The blood examination shows:

Polynuclears	161	61.92 per cent.
Large lymphocytes	37	14.23 " "
Small lymphocytes	36	13.48 " "
Hyaline	21	8.08 " "
Eosinophiles	3	.12 " "
Mast cells	2	.08 " "

Degenerated whites, 10.30 per cent.; no poikilocytes, very little variation in the size of the reds, no nucleated red cells are seen. The distribution of hemoglobin is very irregular.

The feces are extremely foul, small, hard lumps mixed with mucus, and semi-fluid material; proteins are present chemically and microscopically; starches and sugars are entirely digested; the fats are well digested.

The total urine for 24 hours is 1550 c.c. It is pale yellow, turbid, acid; there is no sediment. The specific gravity is 1.007. No albumin is found; bile pigment is in excess; indican in marked excess, plus 3, indolacetic acid moderate; the total solids are 16.31 grams to the liter; urea, 3.5 grams; uric acid, 0.22 grams; chlorides, 6.00 grams; earthy phosphates, 2.00 grams; alkaline phosphates, 3.00 grams; sulphates, 2.00 grams; these equal for daily total of 1550 c.c.; total solids, 25.2; urea, 5.4; uric acid, 0.3; chlorides, 9.3; phosphates, 7.7; sulphates, 3.1. Microscopically there are no crystals, few granular casts, no mucus, few white cells, and no red cells.

After about a month, or a little less, the blood showed; polynuclears, 265, 53.42%; small lymphocytes, 120, 24.19; large lymphocytes, 55, 11.08; hyaline, 47, 9.43; eosinophiles, 7, 0.14; mast cells, 2, 0.04. The hemoglobin per cent. and distribution is normal. There are no nucleated reds, no poikilocytes, no great variation in size of reds; rouleaux formation is good. There are no degenerated white cells. The weight increased 14 pounds in two months.

Case II.—E. E., male, 72 years old, married, gives a history of chronic constipation; is very thin; tongue is coated, dry, and fissured; is neurasthenic; there is loss of mental application, fears, and self-distrust; business is almost impossible. There is insomnia.

Blood examination May 3, 1909			June 25, 1909	
Polynuclears	379	72.19	178	67.42
Large lymphocytes	70	13.33	23	8.71
Small "	49	9.33	39	14.77
Hyaline	13	2.47	12	4.54
Eosinophiles	12	2.28	12	4.54
Mast cells	2	0.03	0	0
	525	99.63	264	99.98
Degenerated whites, 10 per cent.				
Hemoglobin, 90 per cent.			No degenerated whites	
Urine				
No albumin or sugar, excess of bile pigment, marked indolacetic acid, solids 46.60 grams to liter, urea 19.26 grams, chlorides 10.0 grams, hyaline and granular casts, small amount of mucus, few pus cells, few reds. (On rectal examination, prostatitis.)			No albumin or sugar, slight bile pigment excess, no indolacetic acid, urea 28.89 grams per liter, chlorides 12.00, sulphates, slight excess; no crystals, few hyaline casts, small amount mucus, few white cells, no reds.	

Classification. It would be helpful if cases of protein-enterotoxemia could be referred to a few well-defined classes, but this is almost impossible, since they show so many gradations from one type to another; and yet the authors believe that a little study of a case will enable the physician to include it in one or the other of the following provisional types.

1. Neuralgic; with frequent frontal headaches; there may be other neuralgias or actual neuritis; usually the nerves above the waist are chiefly or alone affected; these cases commonly have more indolacetic acid than indican in the urine.

2. Neurasthenic; when in males there is often present a distinctly sexual element, with seminal vesiculitis or prostatitis.

3. Anemic-chlorotic; oftenest found in young women who neglect their bowels and eat imprudently.

4. Dyspeptic, with flatulence, alternating diarrhea and constipation, distress in abdomen or dull pain, ptosis of some of the viscera, chronic appendicitis.

5. Mental; with fears, dulness, rapid exhaustion on mental effort, impaired will and memory, melancholy.

6. Mixed types, most common, but one of the above usually predominating.

Treatment: This subject naturally falls into two main divisions, the dietetic and the medicinal. The most valuable hints for diet are derived from the study of the feces and the tests of hepatic and pancreatic efficiency; for if the patient is making a good use of starches and sugars, while fats are fairly well digested, the indications are clearly to cut proteins to a minimum, make cereals and other starches the main reliance, and supply assimilable fats guardedly. It will not do to exclude proteins from the diet entirely, for these patients are often losing weight, and without proteins in the food they will consume the body's own proteins and

continue losing weight. A little lean meat once a day, or milk, or vegetables rich in protein may be allowed. The weight must increase in such a case if improvement is to take place, and the patient should have a special suit of clothes and a particular day of the week and hour of the day for taking his weight, always on the same scales; after the first weighing the clothes should be rolled in a bundle and weighed at home, which will give a constant factor to subtract from the various weighings to reckon the actual weight without clothes.

It is absolutely necessary to supply ferments; otherwise even the small amount of protein allowed will putrefy and delay improvement. All the strong proteolytic ferments have a pronounced action on milk and upon proteins of vegetable origin.

Many patients miss the protein from their diet if too much restricted, and will rebel, and since the patient's co-operation is most important this must be taken into consideration. Perhaps nothing is quite so good in such cases as gelatin. It may be prepared acceptably in many ways, simply dissolved in beef broth, or given as calves'-foot jelly or other jellies, or as Bavarian and other creams for dessert. Gelatin is peculiarly free from aromatic elements which furnish indican and indolacetic acid, and it is bulky and well tolerated. Aldor[35] has used it with success in 60 cases of intestinal catarrh. Other cases do well on junket and whey, the latter given cold, flavored with lemon. Buttermilk is an excellent article of diet, and may be taken *ad libitum*. Fermented milks are on the border line between food and drugs, for they are supposed to nourish and at the same time to aid in disinfecting the intestine. In such fermented milk the casein is already converted (to about 50 per cent.) into peptone and albumose; lactic acid is about 1.0-1.2 per cent.; calcium phosphate is in an easily absorbed form, and they are particularly useful when the stomach is also deranged, as in anorexia nervosa, and subacute gastritis. Gout and arteriosclerosis are often associated with intestinal putrefaction, and for these conditions the fermented milks are also useful,[36] North[37] in some cases employs suspensions of butter and lactic acid bacilli in maltose broth for flushing out the colon. Nutritive enemata may be found useful, but rectal alimentation is seldom needed for these cases. Where hyperacidity and spasmodic pain are important symptoms, olive oil is frequently of service, either swallowed or taken through a tube, best given hot.[38] Tea, coffee, and alcohol are almost always to be forbidden, and copious drinking of distilled water encouraged to the utmost and kept up for weeks and months. Other cases will require other diets, and it often taxes the physician's ingenuity to suggest something with the patient likes and which he really ought to have.

Drugs: The indications for drugs are chiefly six: 1, to clean the bowel thoroughly; 2, to stimulate the liver to produce more bile and of a more fluid quality; 3, to supply ferments; 4, to disinfect the alimentary canal; 5, to care for the stomach condition; 6, tonics.

1. The immediate need is for a clean bowel, and this may be obtained by calomel or calomel with podophyllin, best given in 0.01 every hour for six doses, and followed by a saline the morning after, with a full glass of cold water. But it will not do to stop here. Increased catabolism is an absolute need,[39] and either cathartics or diuretics or both must be taken for a long time. When the constipation is accompanied by too small a total daily urine, of high total solids, salines may accomplish the double purpose of flushing out the bowel and causing the excretion of more urine, but as a rule it will be better to give salines only as diuretics, except with obese patients, cleansing the bowel otherwise. For the latter purpose nothing gives better satisfaction than phenolphthalein, either in the tablet form or as syrup, the latter especially for children. Usually one or two tablets every night will suffice, but more can be given, and after daily thorough defecation has become the rule, the quantity of the drug may be reduced, giving a tablet once every other day or twice a week. As opposed to all other purges, phenolphthalein does little if any damage to the intestinal wall, materially decreases the numbers of bacteria, and produces a copious outpour of the lymph in the deeper parts of the mucosa and its lymph channels.[40] But in some cases other cathartics are necessary, and a proper pill may be alternated with a tablet of phenolphthalein, and the laxative effect of certain articles of diet, like shredded wheat biscuit, may be used to aid the drugs. Consistent and persistent deep breathing will also aid in the attainment of this object, but it is difficult to persuade the patient of it. The various preparations of bile salts, and combinations which contain them, are efficient and convenient means of obtaining several kinds of action at once. The offensive breath, coated tongue, pain in the region of the liver, foul odor of the feces, flatus, and similar symptoms, all tend to improve as soon as more bile, of more fluid quality, enters the intestine daily. As the catarrhal condition of the upper part of the small intestine improves, the enterohepatic circulation of bile salts is facilitated, peristalsis becomes more regular, and cathartics in reduced frequency maintain the advantage gained.

3. Since the chief reason for the failure of the proteins to digest, whence come all the other troubles, is often a lack of the normal ferments, a very clear indication is to supply such ferment. The administration of ferments should be kept up for several months while proteins are cautiously added to the dietary and their digestion watched by frequent tests of the feces and the urine. When fat is not well digested, alkalies are indicated.[41]

4. Intestinal disinfection is a difficult subject. Salol, naphthalene tetrachloride, some of the guaiacols, creosote, and sulphocarbolates are all useful at times; perhaps the sulphocarbolates are most uniformly useful, keeping watch against any tendency to constipate. Schmidt[42] has suggested a simple and ingenious method of disinfecting the bowels which it might be well to try. He finds that agar will take up about 12 per cent. of hydrogen peroxide and give it off slowly in the intestinal canal. Such a jelly, flavored to taste, swallowed in rather large lumps without much chewing, may be a valuable addition to the medication, particularly if diarrhea is a marked symptom.

5. The conditions in the stomach should always be studied. Hyperchlorhydria and gastrosuccorrhea are well controlled by eumydrin, as shown by Tedeschi in 1907 and Massini in 1908.[43] It may be given in doses of 0.001 t.i.d., and is best combined with sodium citrate; it is more efficient than atropin and less toxic. For the opposite condition Ynkawa[44] has lately claimed that suprarenal extract strongly increases the flow of gastric juice and the production of hydrochloric acid, except in complete anacidity. Of course, the well-known and established

measures may be required in addition, to say nothing of repeated use of the stomach tube.

6. Tonics are required in the majority of these cases; anemic cases usually do best when both iron and arsenic are given. A convenient and efficient way to administer iron is by Blaud's pills after meals, plain or with arsenic. Strychnin is best avoided in most of these cases, for the heart is apt to be irritable. As a rule, tonics are most needed at the beginning of the case and should be dropped as soon as there is a decided gain in weight and the patient is habituated to a diet which suits him.

Tuberculous Peritonitis.—Noble, in concluding an article on this subject, says: 1. Tuberculous peritonitis of the serous variety is best treated by laparotomy. 2. Great care should be exercised in making intraabdominal manipulations and examinations, not to cause abrasions. 3. In the adhesive variety no attempt should be made to disturb the adhesions. 4. The less the tissues are handled the better will be the results. 5. Removal of the primary focus of the tuberculous peritonitis when possible should always be performed, *i.e.* appendix, tubes, etc.—*Illinois Medical Journal.*

NUCLEIN BY INTRAVENOUS INJECTION IN THE TREATMENT OF TUBERCULOSIS.

By EDGAR P. WARD, M.D., Ph.D.,

ST. LOUIS, MO.

PROFESSOR OF EMBRYOLOGY AND CLINICAL MEDICINE, HIPPOCRATEAN COLLEGE OF MEDICINE.

In reviewing the literature upon tuberculosis, I have been unable to find any reliable information upon the condition of the blood in tuberculous subjects. Beyond the mere statement that the patients are anemic, I have been unable to find any original research that would recognize or give a reason for the similarity of the condition of the blood in tuberculous patients of a comparative known degree of infection. We recognize the fact that the mucous membrane of the bronchioles and air vesicles are, in the tuberculous, necessarily impaired; consequently, we have the physiological use of just that much tissue eliminated, the area of which is more or less rapidly increased as the pathological condition progresses. It is the gradual diminution of the normal tissues and the increase of the pathological conditions, eliminating the possibility of the patient securing a sufficient amount of oxygen to supply the normal requirements of the body for this element, that gradually produces the anemic condition as witnessed in these cases.

If the physician will study the embryological development of the body, and recognize and realize how dependent all the tissues of the body are upon the cellular development and rejuvenation, so to speak, he will realize the necessity of treating tuberculosis, as well as all other pathological conditions in which there is a destruction of tissue, by creating new cells in the blood, as well as elsewhere, to take the place of those that are cast off in the pathological excretions.

Our system of medication, in these cases, has been limited largely to such as is given per os, and we are dependent upon the absorption of the same through the gastrointestinal system, never knowing the exact portion that may be absorbed and carried to the tissues of the body, nor the chemical changes that may take place by the action of the gastrointestinal secretions thereon. There is always more or less impairment of the digestive system in all these cases. Realizing this, I have concluded that the way to get the full benefit of such remedial agents as may be our choice in using, is by their introduction direct into the circulatory system.

I have found in the tuberculous subject, in addition to the presence of the tubercle bacilli and the general clinical symptoms that are familiar to us all, a marked change in the blood, a change that may be recognized by any one and which does not require any unusual laboratory equipment. The normal specific gravity of the blood varies between 1.055 and 1.060. In every case of tuberculosis that I have examined in the past two years, I have found a decrease in the specific gravity of the blood, with a corresponding decrease in the amount of hemoglobin. Physiologists tell us that the blood in one thousand parts contains 784 parts of water and 216 parts of solids; the greater portion of the solids is composed of corpuscles, and the analysis of 1000 parts of moist corpuscles shows water 688 parts, and solids, organic, 303.88, and mineral 8.12. Of the solids the most important is the hemoglobin, it constituting more than 90 per cent. of the organic

matter of the corpuscle. When we have a decrease in the number of corpuscles, we have a corresponding decrease in the amount of the hemoglobin, their most important constituent, and the corpuscles being decreased, we have a consequent decrease in the specific gravity, and the percentage of the decrease of the hemoglobin may be computed easily from the specific gravity as given in the table below.

The simplest and most available way to estimate the specific gravity of the blood is that of Hammerschlag, a modification of the Roy method. Chloroform is heavier than blood; benzol or benzine is lighter. Mix in a hydrometer glass such quantities of the two so that the specific gravity, taken with an ordinary hydrometer, is 1.058, that of normal blood. Puncture the ear or finger, draw a drop of blood into a dropper, then blow it out into the chloroform-benzol mixture. The blood does not mix at all with these liquids, but floats like a red bead. If it sinks to the bottom, add chloroform; if it floats at the top, add benzol, adding one or the other of these fluids until the drop finally remains stationary in the body of the liquid, showing that the specific gravity of the drop is just that of the surrounding liquid. Then gently place the hydrometer in the fluid, and the specific gravity of the fluid is shown, which is identical with the specific gravity of the blood contained therein.

The specific gravity of the blood plasma varies very little from any cause (except in dropsical conditions), the hemoglobin composing more than 90 per cent. of the organic solids of the corpuscles, consequently the specific gravity of most non-dropsical patients varies in accordance with the hemoglobin.

Some care should be exercised in taking the specific gravity: (1) Have the inside of the hydrometer glass perfectly clean and dry, otherwise the drop of blood may cling to the glass and flatten against it. (2) It is usually well to have more than one drop of blood in the fluid in case of any mishap to the first one. (3) Add the chloroform, if required, drop by drop. This may be dropped direct into the containing glass. Add the benzol, drop by drop, using a long pipette and gently placing the end at the bottom of the glass container. By adding these fluids in this manner you avoid the necessity of stirring the fluid in order to have it thoroughly mixed, and thus avoid the danger of breaking up the drop of blood. (4) Avoid having any air in the blood drop; this can generally be seen either in the capillary tube or after the drop is in the mixture.

In dropsical cases we must use some form of hemoglobinometer. In other cases, I do not see why this method should not be adopted, as it is easy, accurate, and a quick method of calculating the specific gravity.

Hammerschlag's Table.

Specific Gravity.	Hemoglobin Percentage.
1.033-35	25 to 30
1.035-38	30 to 35
1.038-40	35 to 40
1.040-45	40 to 45
1.045-48	45 to 55
1.048-50	55 to 65
1.050-53	65 to 70
1.053-55	70 to 75
1.055-57	75 to 85
1.057-60	85 to 95

Modified Table from Schmaltz.

1.030	20
1.035	30
1.038	35
1.041	35
1.0425	45
1.0455	50
1.048	55
1.049	60
1.051	65
10.52	70
1.0535	75
1.056	80
1.0575	90
1.059	100

Apparently a degree of specific gravity means much more at the top of the scale (*i.e.* 6.6 per cent.) than at the bottom (1 2/3 per cent.). These tables, while not absolutely correct, are near enough for all practical purposes (Cabot).

With a decrease in the specific gravity of the blood we also find a decrease in the number of red blood corpuscles. Not only do we find a deficiency in the number, the normal of which is five million in the male and four and one-half million in the female to the cubic millimeter, but we find these cells very much deformed, poikilocytes, as they are called. Careful observation will show that the percentage of poikilocytes to the normal blood-cells increases in accordance with the severity of the disease, *e.g.* if the specific gravity of the blood is 1.045 the percentage of hemoglobin will be about 50 per cent., and blood examination will show that coincidently about 20 per cent. of the red blood-cells will have become poikilocytes, the presence of which simply indicates that there has been a separation of the hemoglobin from the cell, it having gone to form some of the more deleterious portion of the plasma. As a consequence of the loss of this hemoglobin, we have marked deficiency in the oxygen-carrying power of the blood, thus depriving the cells of that element upon which they are so dependent. Under the influence of the nuclein-saline solution the poikilocytes rapidly disappear from the circulation, the hemoglobin eliminated by the liver as bilirubin and biliverdin; the deformed cells being replaced by new and healthy erythrocytes from the normoblasts more rapidly than is possible under any other form of treatment as yet devised.

I have been using nuclein solution containing approximately six grains of sodium tritico-nucleinate to the ounce, standardized to one milligram of organic phosphorus to each cubic centimeter; using this in physiological salt solution made up as follows: Calcium chloride, 0.25; potassium chloride, 0.10; sodium chloride, 9.00; water, 1000.

I have been using this as a vehicle for the nuclein for the reason that it conforms to the normal specific gravity of the blood; distilled water will act as well if it is preferred, but I believe if our chemists could prepare a salt that would, in breaking up, give up its oxygen, that the effect of the nuclein would be greatly enhanced. Oxygen is what the tissues require, and if it can be introduced directly into the blood, the pathological condition is attacked at its base. The red blood-cells are only the carriers of the oxygen in loose combination with hemoglobin. The cells of the body are crying for oxygen, and having a sufficient supply they will soon take on such a healthy growth that the pathological condition will be greatly minimized, if not cast off altogether.

It has been taken heretofore that the administration of nuclein produces good effects chiefly by inducing leucocytosis. The value of nuclein given intravenously depends not only upon this fact, but in my opinion even more upon its upbuilding effects upon the erythrocytes and hemoglobin.

All other investigators have begun with the idea that the cure of tuberculosis depends, in great measure, on promoting leucocytosis. Now, leucocytes, acting as phagocytes, can take care of tubercle bacilli by surrounding and destroying them, just as they attempt to do with other foreign bodies; but the tubercle bacilli of themselves are of comparative minor importance—it is the effect of their products which we must overcome. Death

c No change, patient sinking rapidly.
d No examination.

occurs in tuberculosis from either (*a*) chronic sepsis from mixed infection, or (*b*) profound anemia, which results from the action of the toxins (or of the bacilli themselves, it may be) upon the erythrocytes, so diminishing the oxygen-carrying properties of the erythrocytes that the patient literally dies of oxygen starvation. By combating the growth of sepsis, the nuclein-produce leucocytosis may reduce the danger from mixed infection, but my experience impresses me more and more with the importance of the secondary anemia.

Now in the tables presented, it is clearly shown, first, that following the intravenous injection of nuclein, the percentage of hemoglobin is markedly increased; second, that the number of red cells is decidedly increased, and third, the specific gravity of the blood is almost uniformly brought up to, or near, the normal.

This is an important step in the treatment of tuberculosis, for it means that if patients can be subjected to treatment before mixed infection occurs, the blood may be easily brought up to normal by this treatment, thus increasing tissue-resistance. My investigations thus far suggest the possibility of there being a nucleinic index of the blood, the exact rating for each individual varying, of course, in degree.

In the process of development of erythrocytes from normoblasts the rapidity of the extrusion of the nuclei may be hastened or retarded by the amount of free nuclein in the blood (or if not nuclein then some unknown agent of like character) diminishing as the amount decreases and vice versa. If, then, the amount of nuclein be increased or the theoretical nucleinic index raised by the intravenous injection of nuclein, a problem of vast therapeutic importance is solved. All this, however, is, of course, purely theoretical. Yet as a practical result we do see exactly these results obtained, so whether or not the theory is a good one, we have the demonstration complete, in that its effects are exactly what is needed in the secondary anemias, even if not in the primary.

In the technique of intravenous infusion surgical cleanliness must reign supreme. Too much care cannot be exercised to have the parts thoroughly aseptic. Scrub the parts carefully with some good antiseptic soap, and wash off with alcohol. Apply an alcohol pad over the parts until ready to make the injection. I use an ordinary infusion bottle, with six feet of rubber tubing, about one-quarter of an inch in diameter, and a No. 18 or 20 saline solution needle. The needle should be sharp, and with not too long a cutting edge. Keep the needle in alcohol when not in use.

The bottle and tube should be sterilized before placing the solution in it. Allow one ounce of the solution for the bottle and one ounce for each twenty pounds of the weight of the patient. Now place the infusion bottle, tube, and needle, all attached, into a water bath and allow the same to reach the boiling point. This will give a temperature of the infusion at about 110° F. Then place the amount of nuclein solution to be used in the bottle and thoroughly mix it with the salt solution by agitation. Apply an elastic ligature about six inches above the elbow. This should be drawn tight enough to swell the vein. I use an ordinary rubber band about one-quarter of an inch wide. When the vein has become prominent, remove the pad, and spray the surface with chloride of ethyl. This insures practically a painless operation. Introduce the needle at an angle of 45°, first passing it through the skin and then into the lumen of the vein. If the needle is passed freely into the vein, there will be no trouble with the flow, which must be slow and continuous. Place the infusion bottle at a height of the patient's head, when he is in a sitting posture. About twenty minutes is required to introduce six ounces in this manner.

When the solution is nearly exhausted, shut off the flow and remove the needle by gently withdrawing it, at the same time using gentle pressure with gauze over the point of puncture. Having removed the needle, secure the gauze with adhesive strips, which may be removed in a few hours.

I use the median cephalic or median basilic vein. If care is used, a larger number of injections may be given in either vein in a very short space. I have given as high as sixty injections in one vein, all the time operating within a space of one inch, without harming the vein whatever. The dose of

e No change.
f Refused further treatment.
g No change from last report.

nuclein must be regulated by the results that are obtained upon the blood.

Of the 48 cases that I have been treating in this manner, I have had five deaths. In no case where I have been unable to obtain favorable results have I noted that the treatment has been harmful.

I have reported but 15 out of 48 cases, for some of them have not been under observation a sufficient length of time to warrant passing judgment upon them. All of my cases were such as are met with in private practice.

I may sum up the results of the treatment as follows:

1. If there is not a net increase in the percentage of hemoglobin in two weeks' time, we do not expect any permanent result.

2. Even where there is no net increase in the hemoglobin, the treatment aids in keeping these people upon their feet.

3. With a constant increase in the percentage of hemoglobin, when the same has reached 85 per cent. to 100 per cent., and remains there for one month after all treatment has ceased, the patient may be declared well.

PERSONAL EXPERIENCES WITH A FEW CASES OF PELLAGRA.*

By PAUL V. ANDERSON, M.D.,

Morganton, N. C.

It is useless to go into an historical discussion of pellagra, as so much has been written recently on this subject. The disease was first diagnosticated in the Western North Carolina Hospital for the Insane by the Superintendent, Dr. John McCampbell, in 1908, and I am indebted to him for permission to report these cases.

The predisposing causes of the disease are supposed to be ill health, poverty, alcoholism, poor hygienic surroundings, and venereal excess. Since the discovery of the disease more than a century ago, the opinion has gained ground among those who have studied the subject most carefully that the causative factor—whatever it may be—is taken into the body with some product of Indian corn. The specific cause of the disease is, however, unknown.

The pathology is indefinite. No specific, morbid changes are seen in acute cases. Marked changes rarely occur until the disease has existed three or more years. Among these changes are atrophy of the subcutaneous fat and muscles, and a tendency to atrophy and fatty degeneration of the heart, liver, spleen, and kidneys. Abnormal pigmentation is seen also in the muscles of the heart, the spleen, and the liver. In the intestines there is atrophy of the muscular coat, hyperemia, and ulceration. The changes in the nervous system show in some cases hyperemia—in others, anemia and edema. There are inflammatory changes in the meninges; degeneration of the lateral columns in the dorsal, and of the posterior column in the cervical and in the upper dorsal region. Often there is pigmentation of the cord and of the spinal and sympathetic ganglia. The central canal of the cord is frequently obliterated. It is said that the degeneration of the motor ganglia cells is more marked than the sensory. The cells of the anterior cornua are especially affected. The cells of the posterior cornua are also affected, but here the disease is not so marked. (Tuczek.)

Pellagra may be either acute or chronic. Both forms occur in spring or early summer, and, in the chronic cases, a recurrence of the symptoms appears at the same time each year. The disease frequently exists for several years before a fatal termination. In this disease the cutaneous, digestive, and nervous system are chiefly affected; the gastrointestinal symptoms being noted first, and, as a rule, these symptoms occur from one to four weeks—in some cases longer—before the erythema makes its appearance. The earliest symptoms are manifested by nausea; sometimes vomiting and anorexia, which occasionally lead to absolute refusal of food, and necessitate forced feeding; or, there may be an excessive craving for food. Many of our cases have shown excessive thirst, but few of them showed sitiophobia. Frequently there is a painful, burning sensation in the esophagus. Stomatitis is frequently seen. This

*Read by invitation before the Philadelphia County Medical Society December 22, 1909.

usually appears early. It is similar to salivation and is frequently severe. The tongue, in a majority of cases seen by us, has been smooth, beefy-looking, and glistening. In many cases it looked as if it had been scalded. In one, there were purplish spots on the tongue. The buccal mucous membrane in many cases was reddened and there were aphthous sores at the corners of the mouth and on the lips. Diarrhea is always present at some time in the course of the disease but, at times, it alternates with constipation. The stools are serous, green, and slimy, and there is an intensely disagreeable, and, I have thought, at times, a characteristic, odor. These stools vary from a few to thirty or forty in twenty-four hours when the disease has reached its height. In two cases there was marked hemorrhage from the bowels. Meteorism has appeared frequently and pyrosis a few times. Lombroso says that pyrosis is never absent. These symptoms exist with increasing severity for a month or more before the erythema appears.

The erythema, which is always symmetrical as to location, appears first on the dorsal aspect of the hands and that part of the dorsal aspect of the forearms not protected by clothing. In many of our cases, this has been the only seat of the lesion. In one case, it extended along the ulnar aspect to and including the olecranon. The face, the back of the neck, and the shoulders may be affected. We have not seen the lesions on the feet. In three cases the palms of the hands showed the lesion, and it is said that the bony prominences wherever the clothing touches are frequently affected. In no case have we seen the characteristic erythema on the body, although this has been reported. The erythema appears in the spring or early summer and is almost identical in appearance with sunburn. In fact, these patients think their hands are sunburned. One said, "I picked blackberries one day and the next day my hands were sunburned;" and a country doctor wore gloves when the lesions first appeared and thought his hands improved. It does not disappear, however, like sunburn, with the exfoliation of the epidermis, but increases, and after a few days, but sometimes much longer, it begins to fade. If the case be mild, exfoliation occurs in fine flakes; if severe, in large layers. The affected area, after exfoliation has occurred, is purplish, smooth, glistening and soft; in some cases the lesion presents the appearance of a burn of the first degree. This purplish hue may be replaced by liver-colored pigmentation, or, after several months, the skin may look very nearly normal, but the normal lines of the skin are permanently obliterated. As the attacks recur, the hands become wrinkled, hardened, and leathery. Exfoliation occurs usually only once in a summer, but in one of our cases, the hands peeled three or four times. Mild relapses may occur as late as October. Two forms of the skin affection occur—the moist and the dry—but they differ only in degree. In the moist form, vesicles or bullæ are present, but when these break, the hands look raw and are painful. As a rule, however, the patients suffer very little discomfort from the lesions, but some complain of severe itching and burning.

Nervous symptoms usually occur early in the course of the disease. There is headache, chiefly occipital; pain in the back and in the back of the neck; tenderness along the spine, and tender spots in the lumbar region, the tenderness occasionally being greater over the right kidney. Vertigo, paresthesia, hyperesthesia, muscular weakness, and, as a rule, uncertainty of motion are observed. The cutaneous reflexes are variable and the pupillary reflexes inconstant, although in our cases there has usually been a tardy reaction to light and to accommodation. The deep reflexes may be normal, exaggerated, or lost, but usually they have been actively exaggerated. The patellar reflex has been more active than that of the biceps and triceps. In no case have we found true ankle clonus.

As the disease progresses, the muscular weakness becomes more pronounced, especially in the lower extremities. In some cases the patients were unsteady in their gait and did not seem to be confident of themselves. They walked with the legs widely separated and shuffled along in a tottering way—"spraddle legged"—as one of our patient's husband expressed it. Marked motor agitation is usually observed. While able to be up, the patients walk around the room constantly; coarse tremors are noticed in the head and in the extremities, and the tongue when protruded is tremulous. These tremors are more marked in the upper than in the lower extremities. As the disease progresses, the tremors become more violent, and, though bedridden, the patients are continually in motion. There is more or less incoordination in the upper extremities and the movements are distinctly athetoid in character. At times, the clonic convulsive movements give way to tonic spasms which last for a few seconds, then there is a period of quiescence before the clonic movements begin again. We have had no case of true convulsions. These patients are constantly picking at the bed clothes. They will not allow the cover to remain on them and throw it around in a disorderly way. As death approaches, there is generally present spasticity of the muscles, and, in many cases, marked opisthotonos.

The mental symptoms do not, as a rule, become pronounced until the second or third attack of the disease. In some cases there has been a mask-like expression on the face, while in others extreme apprehension has manifested itself in expression, speech, and behavior. In only one case was the patient cheerful. Emotional instability is frequently marked. Memory defects are present. Comprehension is reduced. Clouding of consciousness is often observed and there is psychomotor retardation as well as disorientation as to time, place, and personal identity. In severe cases the patients have no regard for cleanliness and soil their beds with urine and feces. Quite a number are suspicious, resistive, and irritable. The speech is slurring, and, in the last stages of the disease, there is unintelligible muttering delirium and amentia.

The delusions are varied; but are usually depressive, apprehensive, and painful. One patient thought that she was going to be shot; another that he was going to be hanged. In only two cases have the delusions been self-accusatory. Auditory and visual hallucinations are prominent. One patient saw her children and talked to them, while another thought she heard God and the devil talking to her. Suicidal impulses are common. One patient attempted to throw himself in front of a train while being brought to the hospital. Another tried to butt her brains out against the wall; while still another threatened to smother herself, and a physician attempted self-destruction by taking laudanum.

All of the cases which we report have given a history of ill health for two or more years before the mental symptoms developed, and most of them have had the skin lesions and the digestive disturb-

ances with nervous symptoms for at least two years before admission. The majority of cases occurred in farmers and farmers' wives for the reason that the population of our State is chiefly rural. Some were exceedingly poor, but three cases occurred in people who were well-to-do. The duration of insanity before admission was variable. There is a history in one case of periodic mental disturbance for six years. The age of the oldest patient was fifty-four; of the youngest, twenty-four. In many cases there has been a history of insanity in the family.

Case I.—Admitted December 12, 1907; he was 38 years old; had been married 13 years, and had one child who is 12 years old. He had had a common-school education. A former attack of mental disturbance had occurred fourteen years before. He had been insane six weeks before admission. The condition was supposed to be due to spinal disease. He also had had indigestion and spermatorrhea several years. The present attack first manifested itself in talk about religion, increased irritability, neglect of business, incoherent and irrelevant talk, occasionally crying, insomnia, motor restlessness, the thought that the Lord raised him above all other men, and that he was omnipotent. He had fought with two or three men and tried to cut one, and talked of suicide. At the time of admission, there were no skin or alimentary canal symptoms of pellagra, no history of erythema or diarrhea at any previous time, but complaint of indigestion, nervousness, spinal disease, and spermatorrhea for several years. He was admitted in a good state of nutrition. During a stay of a few months in the hospital he was only neurasthenic, hypochondrical, and complained of indigestion and backache. The physical and mental condition rapidly improved. He gained weight from 160 to 190 pounds, and went home April 4, 1908, apparently well. He returned May 21, emaciated, with diarrhea, a mouth sore, and increased salivation. The backs of the hands showed pellagrous erythema and also a patch on the bridge of the nose extending to forehead and over each malar prominence like the three leaves of a clover stalk. He had done little work on farm and was little exposed to the sun's rays. After readmission, he rapidly lost weight; the diarrhea became more marked, and there was an increasing distaste for food; he had difficulty in swallowing, became extremely apprehensive, restless, sleepless, and somewhat self-accusatory. He had the delusion that he had hydrophobia; he churned the saliva into foam, and begged every one not to come near him, as he feared he would bite them; something was in his throat, he thought, which prevented his swallowing. The distaste for water was marked; he became extremely maniacal, noisy, and emaciated, and died June 24, 1908, ten hours after a profuse hemorrhage from the rectum, exsanguinated, and seemingly because of rapid loss of blood. It is seen that death occurred June 24; that he went home April 4—ten weeks before—a splendid specimen of physical manhood, free from all pellagrous signs.

Case II.—The patient was a young woman of 26; a farmer's wife; her mother was insane; she was very much emaciated and had a dull, vacant expression on her face. There was a previous history of ill health for two years and diarrhea accompanied by skin lesions on the hands and arms for the two summers preceding admission. A week before admission she became violently disturbed, was restless and apprehensive that she would be hurt, and had to be tied in a chair to keep her quiet. She ate little. The patient was admitted July 14, 1909. At that time there was a reddish, scaly eruption on the dorsal aspect of the hands. This eruption extended along the ulnar aspect of the forearm to and including the olecranon. The palm of each hand was fissured and presented a blackened, scaly appearance with marked desquamation. The patient was exceedingly restless; coarse tremors of the head and extremities were seen. The deep reflexes were exaggerated to a marked degree; the gait was uncertain and spastic. The pupils were dilated and reacted sluggishly to light. There was confusion; she was resistive and at times catatonic. She was disoriented as to time, place, and personal identity; was always apprehensive and tried to hide. The delusions and hallucinations were of a painful character. She soon became bedridden, but was kept in bed with difficulty; she tossed the covers about the room; was exceedingly untidy in her habits and there was severe diarrhea. Anorexia was marked; thirst was excessive. The nervous and mental symptoms became more marked; insomnia was persistent; the tremors were pronounced, and, at times, became clonic convulsive movements. Occasionally tonic spasms occurred. As death approached, she was mute, stuporous, and helpless, and there was opisthotonos. She died September 29, 1909.

Case III.—The patient was a farmer's wife, 25 years old. There was no history of insanity in the family, but there was a history of ill health for two years preceding admission. The mental trouble began October 12, 1908. The erythema appeared on the backs of the hands at the same time, and there was a slight diarrhea. The patient's husband was sure that this was the first attack of the skin trouble and of the mental trouble. She talked foolishly; was low spirited; lost her appetite; the mouth was so sore that she could scarcely eat; and she picked at her hands until they became sore. The husband stated that "for five years she had not eaten two pounds of stuff made out of corn." She was depressed on admission; showed typical lesions on the backs of her hands; later became maniacal and very exalted; was absolutely incoherent; at times, had lucid intervals; at times, was stuporous; motor agitation was marked and tremors of the extremities especially noticeable. The deep reflexes were exaggerated, especially the patellar. A tap at any portion of the body would cause more or less tetanic contractions. Insomnia was persistent and diarrhea severe. The tongue was red, smooth, and looked as if it had been blistered. In some places, purplish spots were seen on the tongue. She sometimes refused food; at others, ate ravenously; diarrhea was severe and emaciation became extreme. As the skin lesions disappeared the mental and physical condition improved. The patient was in a jolly and happy frame of mind; gained flesh rapidly; remembered much that had taken place during her illness; realized, however, that her mind was not right. Nine months after admission she was well enough to go home. There was some mental deterioration, however, and the backs of the hands still showed the result of the inflammatory changes. This is the only patient since the disease has been recognized here who has become well enough to go home.

Case IV.—This case is different from the other cases in that there was a history of erythema accompanied by diarrhea which occurred first eight years ago and had recurred each summer since that

time. The mind did not become upset, however, until six years ago, but, since then, there had been each year mental disturbance coincident with the appearance of the dermatitis. The patient was alternately excited and depressed, and, about September of each year, when the hands improved, the mental symptoms also cleared up, and her condition was approximately normal until the next summer. On admission there was typical erythema on the hands. The abdomen was distended and there was a slight diarrhea; the deep reflexes were markedly exaggerated; the gait was spastic; she walked with difficulty and with feet wide apart; she was intensely excited for a while after admission, but four months after admission was more or less depressed and emotionally unstable. The erythema at that time had disappeared from her hands and she had gained forty-three pounds in weight. She was now able to give quite a clear account of her past life; realized that her mind was not yet normal, and showed some signs of deterioration.

Case V.—This occurred in a cultured woman of 57. There was no history of insanity, but there was a history of ill health for two years before admission. She was treated at Hot Springs for rheumatism eighteen months ago and had been in a hospital for nervous diseases twice since January 1, 1909. Two years ago she weighed 165 pounds, but in January, 1909, weighed only 95. The first symptoms noted were indigestion, headache, spinal pains, marked insomnia, nervousness, and loss of appetite. She was easily tired, could not attend to her duties, and was very emotional. She had formerly attended to her husband's business when he was away. She worried over trifles; was suspicious and thought that she was becoming insane; her mind became much disturbed in May, 1909, when she thought she was going to hell and threatened to smother herself; she became noisy, restless, incoherent, untidy in habits, and, at times, had convulsive attacks with cramps in muscles. At these times she had to be restrained in bed. Slight scaliness on the backs of the hands appeared a few weeks before admission. She was brought to the hospital on a stretcher June 4, 1909. Motor agitation was marked and there was an apprehensive look on her face and she refused to speak. Physical examination showed a well developed, fairly well nourished woman, brunette in type; the skin was moist and brownish in color on the dorsal aspect of hands and a few inches on dorsal aspect of forearm. Very slight scaliness appeared on the hands and there was a slight redness on the knuckles; the lips were tightly compressed and there were marked twitchings around the mouth and coarse tremors of the head and extremities, more marked in the upper extremities. The strength of the upper extremities was good; that of the lower extremities impaired. Pupils reacted sluggishly to light and to accommodation. Cutaneous sensibility was impaired. The deep reflexes were exaggerated. Babinski's sign was not present; there was no ankle clonus. The heart and lungs were normal; the abdomen was distended, but no masses could be felt. At times there were marked clonic convulsive movements of the upper extremities which became tonic for a period of a few seconds. This was succeeded by an interval of quietude. As the disease progressed the mental and nervous symptoms were more pronounced. The patient was irritable and resistive; tore up her clothes; pulled out her hair; was untidy and the victim of many painful hallucinations and delusions. The temperature varied from 100° to 102° and sweating was excessive. Anorexia was marked as well as excessive thirst; diarrhea was persistent; a bed sore developed. As death approached there was general spasticity of the muscles with opisthotonos. The patient died from exhaustion July 30, 1909.

Case VI occurred in a cultured woman of 52 and there was no history of insanity in the family, but there was a history of ill health for two years preceding admission. She had been despondent for quite a while and recently lost interest in her affairs; became reticent and embarrassed by the presence of her friends; could not sleep; was apprehensive and asked if she were losing her mind. No history of diarrhea or erythema could be obtained. She was mute for a week after admission, then began to talk and gave a fairly correct account of her past life, although she was confused as to dates and could not answer many questions which she should have known. Soon developed the typical nervous and mental symptoms of pellagra and had a persistent diarrhea. Opisthotonos occurred before death. She died demented, without showing any skin lesion. Two similar cases have been seen in male patients.

Case VII.—The patient was a woman 25 years old, a farmer's wife, well developed but markedly emaciated. There has been no history of insanity in the family, but there was a history of ill health for two years and for two summers preceding admission, erythema with exfoliation on the dorsal aspect of hands, wrist, and back of the neck. The digestive and nervous symptoms were slight. In the last of June, 1909, the eruption again appeared. Vesicles were present on the hands and neck, which, when they broke, left the hands raw. Digestive and nervous symptoms were marked; the appetite was ravenous; the mouth and tongue were sore; salivation was excessive; diarrhea was severe, ten or twelve watery stools a day; insomnia was persistent. She complained of pains in the head, feet, and back; was so nervous that she held a glass with difficulty; the gait was uncertain; she walked in a stiff, stilted way with feet widely separated. She had vertigo and fell once. The mind became upset in August. She was apprehensive; thought that she was going to be shot; talked with Christ and the devil. She had eaten little or no corn bread; ate muffins occasionally. Corn was raised on her husband's farm and stayed on the stalk until late fall; only the best ears were sent to the mill. On admission, September 8, 1909, there was a reddish, scaly eruption on the backs of the hands and wrist. The palms were fissured, dirty, and showed marked exfoliation. Erythema and scaliness appeared also on the back of the neck. Marked coarse tremors were noted in the head and the extremities—more marked in the upper extremities. The patient, after persistent questioning, gave a fairly good account of her past life, but her memory was defective. Comprehension was poor and confusion marked, and there was psychomotor retardation. The tremors at times became more or less clonic convulsive movements and occasionally tonic spasms were present for a short time. As the disease progressed, nervous, mental, and gastrointestinal symptoms became more marked. The appetite was ravenous, but she could not eat on account of difficulty of swallowing. She was kept in bed with difficulty; was very emotional and apprehensive and the delusions and hallucinations were exceedingly painful. She tossed her

clothing about; emaciation was extreme; a slight fever was present; bed sores developed and opisthotonos occurred just before death. She died from mental and physical exhaustion October 10, 1909.

Case VIII.—A country physician was admitted at the age of forty. He presented the characteristic dermatitis; had diarrhea, anorexia, and was so weak as to necessitate confinement to bed. The mental symptoms were well defined; the delusions were depressive, painful, and apprehensive; he feared that he was to be burned alive; was going to hell and the Lord had taken his spirit from him and had made his hands sore because he had been profane and had not lived right. While in the hospital he attempted suicide by hanging. During a stay of two months in this hospital the nervous symptoms improved; the diarrhea subsided; there was a gain in weight of fifteen pounds, and he returned home. The feature of special interest in this case was the fact that for ten years before admission this man had suffered from gastric dyspepsia each summer, attended by loss of weight, although the skin involvement did not show itself until two years before admission.

Case IX.—During the past summer the disease in aggravated form has been observed in one of our old patients—a dement sixty-one years of age—who has been in the hospital for twenty-one years and was insane ten years before admission. For the past two or three years he has been living at a colony building, remote from all cases of pellagra, and contagion during this time is not to be considered.

Urinalysis in cases under our observation has shown nothing characteristic. Examination of the blood reveals the changes incident to secondary anemia, and we have found an increase in the number of lymphocytes, especially the larger cells. The eosinophiles appear to be reduced in number.

I am indebted to Dr. James King Hall for the male cases reported in this paper.

A CASE OF SINUS THROMBOSIS COMPLICATED BY CEREBELLAR ABSCESS AND PURULENT LEPTOMENINGITIS.

By ALFRED BRAUN, M.D.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

We all know that there is a natural tendency among surgeons to report only their favorable cases. But the purpose of case reports is not to advertise one's skill or prowess. They should be written solely for the purpose of increasing our knowledge of the subject of which they treat. The most instructive cases are very often those with the most unfortunate terminations. We learn more from a single autopsy on a case that we have observed very closely during life, than we do from the study of a large number of cases that get well.

The following case has been very instructive to me, and I hope that others may glean a point or two of value from its report:

Robert K., a laborer, 58 years of age, was admitted to Dr. Berens' service at the Manhattan Eye, Ear and Throat Hospital, on July 3, 1909, complaining of earache in the right ear, and pain in the side of the head, for two weeks. Examination showed a thick reddened drum-membrane, with a moderate sized perforation in the anterior inferior quadrant, from which exuded a large quantity of pus. There was some edema of the postero-superior canal wall, and marked tenderness over the mastoid. Temperature 102° F. There was no history of chills or sweats.

A simple mastoid operation was done. A thick dense cortex was found. When this was removed, it was seen that the entire mastoid process was converted into a single abscess cavity, the floor of which was formed by bare sinus wall, a large portion of the inner table having been eroded. The sinus was exposed for about 1½ inches of its extent. The sinus wall was covered with granulations, and in its lower part, a short distance above the jugular bulb, there was a ragged hole ¼ inch in diameter, leading into the lumen of the sinus. The sinus contained a clot. Without disturbing the sinus any further, the neck was scrubbed up, and the internal jugular vein resected from just above the clavicle, to a point above where it receives the facial vein, the termination of the facial vein being also removed. The upper part of the vein was hard, and contained a clot. The lower part was free. The reason for resecting the vein before exploring the sinus, was to avoid the possibility of pieces of infected clot breaking off and entering the general circulation.

Coming back to the mastoid wound again, the cortex was removed over the sinus, above and below, until healthy dura was seen. The sinus was now exposed over an area of 2½ inches. The outer wall of the sinus was removed with a pair of scissors. There was no bleeding. A curette was passed into the upper or torcular end of the sinus, and a long clot dragged out. This was followed by a free return flow. The bleeding was stopped by means of an iodoform-gauze plug. The curette was next inserted into the lower end of the sinus, and another clot dragged out, followed by a free return flow from this end. This was also controlled by means of an iodoform-gauze plug, first inserting a wick of gauze into the jugular bulb, in order to induce clotting in the bulb, thus minimizing the danger of infectious emboli being carried off through the inferior petrosal sinus. The wound was packed, and the patient sent back to bed in good condition.

The temperature dropped to normal the next day, and remained normal for thirteen days. The patient felt perfectly well and had no symptoms whatever. He was up out of bed in a week. The neck wound healed by primary union.

On July 16, thirteen days after the operation, just as we were about to discharge him from the hospital, he began to complain of slight headache. His temperature and pulse were normal. The mastoid wound looked well. He was given phenacetin, and a cold pack to the head, and the headache cleared up.

On July 19 there was a return of the headache, with a temperature of 102.4° F., and a pulse of 72. The headache was most marked in the occipital region. Examination of the eye-grounds was negative. Blood examination showed a leucocytosis of 9700—a differential count showing large mononuclear lymphocytes, 2 per cent.; small mononuclear lymphocytes, 12 per cent.; polynuclear neutrophiles, 82 per cent.; transitional forms, 4 per cent. His general condition was good. He was bright and cheerful.

For the next three days, the temperature ranged

between 99° and 102° F., with a pulse between 72 and 80. The headache varied, being rather severe at times; at times disappearing altogether. There were no other local signs.

On the morning of July 23, the house surgeon called me up, and told me that there was a decided change for the worse in the man. He had had a chill, the temperature going up to 102.4° F., with a pulse of 96. He had become somewhat apathetic. I was unable to see the patient until the afternoon, at which time he showed all the typical signs of an advanced meningitis. It was impossible to rouse him to answer any questions. He lay with his head thrown back, and his legs drawn up, moaning constantly. There was a marked tremor of the arms and legs. Rigidity of the neck. Increased knee-jerks. Kernig's sign. The pupils were equal and reacted to light. The right eye-ground was normal. The left showed slight swelling of the disc, with blurring of its edges.

A blood-count showed a leucocytosis of 15500, differential count showing large mononuclear lymphocytes, 2 per cent.; small mononuclear lymphocytes, 13 per cent.; polynuclear neutrophiles, 79 per cent.; transitional forms, 5 per cent.

A lumbar puncture was made. The cerebrospinal fluid was not under pressure. It was very turbid, and showed, under the microscope, pus cells and the pneumobacillus of Friedlaender.

He died the next morning at 10 o'clock.

Autopsy showed the entire pia bathed in thick, creamy pus, extending to the base of the brain, and down into the spinal canal. The ventricles were full of pus. On the surface of the right lobe of the cerebellum, a short distance behind the obliterated sinus, there was an abscess containing about two drachms of fetid pus. There was no necrotic bone. The edges of the mastoid wound were perfectly healthy.

It is very hard to conceive that a cerebellar abscess of such size could develop in a day or two. The only other assumption is that it had existed for several weeks without any symptoms. There was at no time dizziness, ataxia, nystagmus, or any other cerebellar symptom. This might be accounted for by the superficial location of the abscess. There was very little actual destruction of brain tissue.

There are several possibilities in this case.

It is possible that the cerebellar abscess may have been present at the time of the mastoid operation. It gave no symptoms, and there was no reason for my exploring the brain at that time. Two weeks later, the abscess perforated into the pia-arachnoid space, and started up a purulent leptomeningitis.

On the other hand, it is possible that the cerebellum became infected after the mastoid operation, by extension from the infected sinus. This, however, I do not consider very likely, as the sinus was widely opened, the entire outer wall having been removed, free drainage being established through the wide mastoid wound.

An interesting point in this case was the presence of sinus thrombosis, without chills, sweating, or a zigzag temperature curve. I think this is explained by the presence of the spontaneous perforation in the sinus wall, allowing free drainage from the interior of the sinus into the mastoid cavity.

About one-third of the cases of brain abscess are located in the cerebellum. Out of 100 cases of brain abscess observed by Koerner, its location was in the temporal lobe 63 times, in the cerebellum 31 times, and in both situations 6 times. The cerebellum becomes infected either as the result of sinus thrombosis, as in the present case, or following disease of the labyrinth. Occasionally the abscess occurs on the side of the brain opposite to the diseased ear, in which case it is due to a pyemic metastasis.

156 East Sixty-first Street.

SALIVARY CALCULI.*

By GEO. T. WELCH, M.D.,

PASSAIC, N. J.

In the suprahyoid or submental region there is loose connective tissue, in which is imbedded the parotid, the submaxillary, and the sublingual glands. Their excretory ducts communicate with the mouth, and during twenty-four hours pour out a secretion of from one to three pints of saliva. The source from which the cells of the glands obtain the materials of their secretion is from the plasma of the blood, which is filtered off from the circulation into the interstices. Under the stimulation of the presence of food, the saliva is poured out in abundance, though at other times there is barely enough to keep the mouth well moistened. In 1000 parts of the saliva there are found 5.9 of solids, of which 2.29 are made up of the various salts of potassium, sodium, calcium, and magnesium. The liquids of the body at all times carry in solution substances that are inclined to solidify, should there be an arrest of the circulation in a part, or should there be a roughness of surface from any cause, to which the scarcely dissolved salts and sediments could cling and calcify. From this cause we find arteries clogged, as in arteriosclerosis. From any stoppage of the excretory ducts of glands, therefore, we need not be surprised to find that in time calculi have developed. Thus we have biliary calculi, lachrymal calculi, calculi of the pancreas, calculi of the tonsils, and salivary calculi.

Calculi in the parotid gland are rare, and when they do occur, are due to causes in the duct-radicles, which retard the flow of the saliva. Calculi in the submaxillary and sublingual glands, while also rare, are, nevertheless, more common than those of the parotid. Their ducts discharge beneath the tongue, and from their location they are liable to mechanical injuries by foreign bodies, like bristles, small bones, hair, etc., getting into their apertures. The mucous membrane, and the loose connective tissue in the floor of the mouth, under the stimulus of an inflamed duct or gland, readily takes on cellulitis, and from the congestion it becomes brawny, hard, and, the skin about the chin and throat presenting a shining red appearance, the whole may simulate morbid conditions that might well puzzle an expert.

Such condition I found in a lady, Mrs. E. A. S., to whom I was called on September 24, 1908. Her countenance, which was distorted by a great swelling of the region about the right submaxillary, exhibited much suffering and anxiety. She gave a history of her usual degree of health, up to three months before my visit. About this time, a dentist, who had been treating her for some alveolar disease, had inserted a plate with an artificial tooth, to take the place of one extracted. The plate, she

*Read before the Passaic City Medical Society, November 11, 1909.

said, was rather long and pinched the floor of the mouth, and the gum beneath, and gave her much disturbance. Upon the advice of the dentist she had persisted in wearing it, until the pain and swelling had become so great that she had to desist. It was with much difficulty that I could examine the tongue and mouth, as the cellulitis was intense. The glands, the gum, the tongue were all implicated in the condition, and all the parts were slurred into one compact mass, hard, shining, and angry in appearance. The right half of the tongue was stiff and indurated; the sublingual and submaxillary glands on this side were in the same condition, and I could nowhere find evidence of suppuration. I endeavored with a fine probe to discover the aperture of one of the ducts, but could not do so.

Under an antiphlogistic treatment, with antiseptic washes, etc., the parts showed some improvement, the tumefaction slightly subsiding, and the pain abating. The Morton wave current of static electricity was tried with a measure of satisfactory results, the soreness becoming less, and the size of the diseased part abating, but the tenacity of the cellulitis was not reassuring as to a final favorable issue.

On October 8th a prominent surgeon was called in consultation, who, after a careful examination, pronounced the disease carcinoma, of an inoperable character, and gave a hopeless prognosis. Happily, the progress of the disease did not show the characteristic breaking down of structure that accompanies carcinoma in this locality.

After the surgeon was gone, I debated whether I should attempt a treatment with toxins of the streptococcus erysipelas and the bacillus prodigiosus mixed, or with the *x*-ray. I concluded upon the latter course, since the tumor would be so readily permeated by the *x*-ray in such a superficial position.

I gave the first treatment on October 13, and continued it until a decided redness of the skin on October 23 caused me to desist, until the 29th, when I recommenced it, and remitted it on December 28 for the same reason, until January 3 of last year, when it was used at longer intervals. At first it had been used nearly every day, until the evidence of decided redness occurred, then once in two days, and finally once in three days. In the meantime there was gradual abatement of the more serious symptoms, and the size of the diseased part became reduced one-half. Occasionally I would be able to find the aperture of the submaxillary duct by the side of the frænum linguæ, and could probe it for a short distance, when an ill-smelling fluid would be emitted, but I could not find any of the small ducts of the sublingual gland, although there should have been seven or eight of these opening by the side of the frænum.

In March there was some increase in the size of the tumefaction, and the *x*-ray was given three times a week, but in April and after, the rule was to give it about once in four or five days. The induration between the involved glands gradually dissolved away, until finally, from being such a large, solid tumor, the tongue had become normal and flexible, and the two glands were once more separate, and evidently their physiological life was partly reestablished, although both were yet large and indurated.

July 24 there was a reaction, and the swelling and pain returned. I could not find any aperture, but I felt convinced that there might be some surgical relief afforded, and at my suggestion another distinguished surgeon was consulted on July 28. He, also, was inclined to call the disease carcinoma, and advised against any surgical interference, stating that an operation would be frightfully radical, and strongly advocating instead the continuance of the use of the *x*-ray. During my vacation in August, Dr. Percy H. Terhune kindly continued the *x*-ray treatment of the patient. During September and October I gave the treatment at irregular intervals, the glands having now become so much smaller that there was not the same urgent need of it as formerly.

On October 11 one of those periodical reactions took place, and the floor of the mouth and the submaxillary region became swollen, hard, and painful. Fortunately I was able to discover one of the ducts of the sublingual gland, which, upon being probed, emitted a fetid liquid, much to the relief of the sufferer. The following day I found the aperture again, and also discovered a hard substance imbedded in the duct about one inch back from the opening. In examining this, the probe tore through the wall of the weakened duct, when a large salivary calculus was exposed. After its removal, the probe was carried down to the gland, and with the finger pressing against the latter, I was able to determine that there was no other foreign substance remaining. The submaxillary gland was also examined by pressure from within and without, but nothing foreign was discovered therein.

Presumably the pressure of the dental plate on the gum, and on the floor of the mouth, brought on the inflammation that caused such a frightful cellulitis, which closed up the ducts of the glands and induced the salts in the saliva, at some stage of the disease, to be precipitated and form the calculus.

At this date very little vestige of the original disease is to be found.

Scleral Collapse During Cataract Operation.—Santos Fernández describes twenty-six cases that occurred in his practice. He ascribes the cause to the excessive use of cocaine for, since he has limited the amount instilled to three drops of a 3 per cent. solution, no more cases have occurred. At first he thought that this accident was more liable to happen in weak people, but he has abandoned the view after he has seen it happening in healthy, robust people.—*Chronica Medico-Quirurgica de la Habana.*

Intestinouterine Fistula.—Le Jemtel finds recorded twenty-two cases of intestinouterine fistula. There are three conditions in which this lesion takes place. They are acute uterine rupture during labor, due to uterine action, forceps, or version in attempts at delivery; pelvic abscesses connected with the adnexa or appendix opening into the uterus; and cancerous processes in which the disease eats its way through the uterine walls. In rupture of the uterus the intestine becomes prolapsed through the uterine wound, and the uterine contraction causes strangulation of the intestine, gangrene ensues, and fecal material with gangrenous intestinal masses are discharged through the cervix uteri. In any case the diagnosis is very difficult, the symptoms being simply those of pelvic peritonitis, until the fistula has been established and the fecal discharge takes place. Protective adhesions prevent the discharge of fecal material into the abdominal cavity. Spontaneous cure is very rare, the condition being a very grave one, ending fatally from infection. Prophylactic treatment in case of uterine rupture during labor is immediate hysterectomy before strangulation has occurred. In cases of pelvic abscess, drainage should be secured before the rupture into the uterus has occurred. Once the fistula has become established, irritation of vagina and vulva, with ulceration, occurs, and crises of acute inflammation recur. Only an abdominal operation can give promise of relief, combined with intestinal anastomosis or enterorrhaphy.—*Archives Provinciales de Chirurgie.*

New York, March 26, 1910.

THE BUREAU OF PUBLIC HEALTH.

A REVIEW of the literature which has appeared during the past few weeks in both medical and lay periodicals upon the subject of the proposed National Bureau of Public Health, which was advocated by President Taft in his message to Congress a few months ago, shows a remarkable uniformity of opinion as to the need of such an institution. It is generally acknowledged that such a bureau is needed and that its foundation would do much to improve the health and prosperity of the country. It is, therefore, something of a surprise to learn from the Bulletin of the Committee of One Hundred on National Health for February, 1910, that, in order to push the legislation through Congress during the present session, money to the amount of $25,000 is needed. This statement, too, appears in connection with the fact that letters have been "sent inviting each Congressman to declare his position and to pledge his support" and that "the great majority of responses show a willingness to do so, and many letters are enthusiastic." It is difficult to understand how a reform which the President wants, which the great majority of the Congressmen want, and all of the thinking men and women of the country want, should require such a sum of money to bring about.

Another surprising statement in the same pamphlet is that "there is no Department in Washington disseminating information on how to care for infants, how to prevent or cure tuberculosis, typhoid fever, etc." Though the United States Public Health and Marine Hospital Service possibly is not primarily a department for the "dissemination of information" but rather for actual work in improving the health of the nation, it has in the course of its one hundred and twelve years of existence, not only done much in the way of the prevention of disease, but in its publications has disseminated a large amount of information on prevention and cure. It is therefore to the Marine Hospital Service that the country most naturally turns at this time of agitation for the Bureau of Public Health. A corps of expert sanitarians and medical scientists, this body is surely well equipped to enter even a wider field of usefulness than it now occupies, and if the new Bureau is formed it should be around the Public Health and Marine-Hospital Service as a nucleus. The success of the proposed Bureau requires that it be kept out of politics and be placed in the hands of just such an active, disinterested body of men as this corps has proven itself to be.

A more powerful and far-reaching organization for the care of the health of the nation is needed, and, provided it is properly constructed, the sooner it comes the better it will be for the country. Care, however, must be taken that the new Bureau is a step upward and not downward. The formation of a civil commission in which promotion depends upon political influence and favor will be subversive of the purpose for which the bureau is to be created. Where public health is concerned, the organization in control must be entirely outside of politics, but backed by the full power of the Federal Government. In short it should be a strictly military organization, where the appointments are for life and where promotion depends only upon years of service and efficiency. Such an institution already exists in the Marine Hospital Service, a corps prepared and willing on short notice to be enlarged and to take on the broader duties. No new bureau making the Marine-Hospital Service a subordinate department is needed. All that is necessary, if a bureau, and not a department with a cabinet officer at its head, is desired, is to enlarge the powers of the present Public Health and Marine-Hospital Service. No lay politicians are wanted to care for the health of the country.

NEW ANTIVIVISECTION TACTICS.

DURING the past four sessions of the Legislature of this State, bills have been introduced for the purpose of placing severe restrictions upon the practice of animal experimentation. Fortunately all such bills have been defeated by the sensible arguments of the medical profession. Foiled in these attempts, the antivivisectionists now seek by another method to insert their entering wedge. This consists in a bill which has been introduced into the Senate by Mr. Bayne and into the Assembly by Mr. Goodspeed, "To establish a commission to inquire into the extent and nature of the practice in this State of experimentation on living animals." The text of the bill will be found elsewhere in this issue.

Some of our readers may be inclined to welcome such an investigation on the ground that when once the full details about laboratory procedure are told the antivivisectionists will no longer have reason to continue their occupation. This is a plausible but, we believe, a specious attitude. The example of England is here, as throughout the antivivisectionist movement, illuminating. The movement originated in England, and its adherents in this country are closely following the methods and spirit of their prototypes across the ocean. There they have twice resorted to an investigation of the laboratories. As a result of violent agitation, the first Royal Commission was appointed by Queen Victoria in 1875. After taking elaborate testimony, much of which came from members of the medical profession, who at that time did not appreciate the importance of animal experimentation, the commission advised the enactment of a restrictive law. This was largely for the purpose of preventing imaginary abuses in the future since the testimony showed that there ex-

isted at the time no serious abuses warranting such a drastic measure. It was expected by many people that the new law would put a stop to the unpleasant agitation. Such expectations were never realized. The agitation has raged more fiercely ever since, more and more restriction being demanded. There exist now in Great Britain no less than fifteen anti-vivisection societies.

In 1906 these societies again demanded the investigation of laboratories and King Edward yielded to their demand. After a year and a half a second Royal Commission sat and took elaborate testimony. This has been printed in full and again overwhelmingly demonstrates the absence of abuse. The commission has not yet made its final report, but in view of the violent discussion that has raged for two years over the details of the printed testimony, there is no reason to believe that the report will prove to be a palliative in any degree.

In case the legislature deems it wise to pass the present bill the medical profession will give every opportunity to the commission to learn details of laboratory procedure, for, as every informed physician knows, nothing goes on in any of the laboratories which needs to be concealed from well-intentioned and mentally poised persons, whether professional or lay. Indeed, the details of those experiments are constantly being published in medical books and journals, and are seized upon and distorted by the hysterical or dishonest as evidence of the cruelty of animal experimentation, although they prove the direct contrary. And so it will be with the report of this commission, if the bills are passed. The Coleridges and the Belaises, the *Heralds,* and the *Lifes* will go on just the same; they will scream out that a dog's leg was amputated or its thoracic cavity was opened and will cry for the cruelty of it, all the time ignoring the fact, which they cannot possibly fail to know is a fact, that the animals were anesthetized and felt absolutely no pain. In all this agitation, it should be clearly understood that the antivivisection movement is due rather to a peculiar psychological state in its adherents than to present experimental methods.

THE INTERNATIONAL OPIUM COMMISSION.

The incursion of Americans into the Far East, the fact that the Philippine Islands are now under the American flag, and the varied interests of this country in Asia have rendered the material and physical welfare of the Chinese a matter of considerable moment to the people of this land. For some time American missionaries have been foremost in urging that strong efforts should be exerted to deliver the inhabitants of China from the domination of opium. It was felt that no true progress in any branch of industry or in religion or in culture could be made by races that were largely slaves to the opium habit. In recent years many conferences and discussions on the subject have been held and measures have already been put into force to curb the evil. The International Opium Commission, under the presidency of the American Bishop Brent of the Philippine Islands, sat at Shanghai from February 1 to 26, 1909, and the report of its proceedings has been published recently. The following countries were represented by delegates: Austria, America, China, France, Germany, Great Britain, Italy, Japan, Portugal, Russia, and Spain. The report of the outcome of the conference is a voluminous document, but singularly disappointing in some of its features. For instance, the medical and scientific aspects of the question are not dealt with. China, Japan, and America whose delegations contained each one medical expert, wished to appoint a committee to investigate the matter from these standpoints, but the proposal was negatived by the other countries concerned. However, the Japanese report does consider the subject to some extent from this point of view, and is consequently by far the most instructive and interesting to medical readers.

When the Japanese came into control of Formosa, they found the opium habit more or less general with the population, and, of course, especially with the large proportion of the inhabitants who were of Chinese origin. The suppression of the habit was gradual. From a study of the question at the time of their arrival in Formosa, the Japanese compiled the following statistics: Of all males in Formosa, 6.64 per cent. were discovered to be addicted to the opium habit and the greatest percentage of these was found to be in the educated classes, 39.81 per cent. being in the liberal professions, while the poorer or agricultural classes showed only 2.21 per cent. In the endeavor to elucidate the point as to the temptations which caused the contraction of the habit, the first step was traced in 93 per cent. of the cases to the use of the drug by medical advice. With regard to the treatment of sufferers, there are in Formosa numerous hospitals which admit patients. The most common mode of treatment has been by gradual withdrawal of the drug, although this can hardly be termed satisfactory treatment. Public opinion was at first hostile to the Japanese, but now owing to the judicious measures adopted a strong public sentiment has arisen against the opium habit.

In order to suppress the habit in China these edicts have been promulgated: 1. All smokers are to be licensed. All smokers under the age of sixty are to diminish their consumption by 20 to 30 per cent. yearly, and in ten years time all smoking is to be prohibited. 2. All shops which retail opium are to be licensed, and no new ones can be opened. 3. All Government officials under the age of sixty are to give up the habit as examples to others, being allowed only six months in which to do so. 4. Cultivation of the poppy is to be restricted by, at least, one-tenth a year. 5. The sale of morphine and of hypodermic appliances is strictly prohibited, the penalty for evasion of this law being decapitation. Notwithstanding the severity of the punishment, morphine used hypodermically has been largely employed in the stead of opium smoking, being cheaper and more convenient. The morphine is smuggled into China, the Chinese being adepts at this practice. Estimates of the percentage of smokers in the general population of China vary for the same locality between 20 and 75 per cent.

The report of the United States delegation alludes to the opium-smoking question in this country. It

is pointed out that in the Western States the problem has for long been a serious one. A high tariff on the drug has resulted only in increased smuggling. The report contains some interesting information as to the opium habit among the white population of America. The following statistics are stated to have been collected from twenty-five large cities, in regard to the prevalence of the habit: Of prisoners in large jails, 5.6 per cent.; of the general criminal population, 15.4 per cent.; of prostitutes and their parasites, 21.6 per cent.; of physicians, 2.05 per cent.; of trained nurses, 1.32 per cent., and of the general population, 0.18 per cent. are habitual users of morphine or of opium. It was stated that, although regulations aimed against the habit in the Philippine Islands were strict and enforced, smuggling was carried on somewhat extensively. Resolutions were passed recognizing the sincerity of the government of China in the attempts to abolish the opium habit, and recommending that the rigid laws against it should be enforced without fear or favor.

There is no doubt that it will take time to suppress the opium habit entirely, and the traffic in the drug in the Far East. Certain vested interests are opposed to suppression, but public opinion in all civilized countries is too strong to allow the question of money to stand in the way of thorough reform. Year by year the use of narcotics will be diminished although their employment will probably never entirely disappear. As said before, it is to be regretted that the scientific and medical aspects of the matter were not more closely considered at the conference.

SUGGESTION NARCOSIS.

Though nearly a century has elapsed since Récamier first applied hypnotic sleep to surgical operations, use of this power of mind over mind has never been generally made in surgical practice. Occasionally one hears of the extraction of a tooth or the opening of a furuncle while a patient is under the influence of hypnotism, and in rare instances more extensive operations have been performed. That the use of hypnotism is not necessarily confined to minor or momentary operations is shown by an article in the *Deutsche medizinische Wochenschrift* for February 10, 1910, in which Hallauer reports his experience in Strassmann's gynecological clinic in Berlin. The author does not depend solely upon the use of mental influence to anesthetize his patients, but begins the procedure by giving a few drops of chloroform. When the patient has begun to be drowsy, and has lost to a certain extent her self-control, by gently stroking the forehead and hair and suggesting in a monotonous voice first that she is going to sleep and finally that she is asleep, a thorough hypnotic condition is produced. In some instances the patient falls into a deep sleep, while in others, though remaining conscious, she is quite oblivious of all sense of pain. When, however, the operation is completed, and the patient is told that she is awake, she is able to arise at once, and in the case of one of the simpler procedures, to go to her home immediately, having none of the symptoms usually experienced after chloroform or ether narcosis.

Hallauer has made use of this procedure in over three hundred cases. In 60 to 70 per cent. the results were perfect; in 20 per cent. the effect was only partial, but quite sufficient to permit the operation; while in but 10 per cent. it failed, and chloroform anesthesia was required. He has used the suggestion narcosis in the operations of curettage, dilatation of the cervix, removal of retained membrane after abortion, amputation of the cervix, replacing of a retroflexed uterus, cauterization of carcinomata and caruncles, and many others. In all such procedures gentleness and care must be used, and the patient must be told that she is being washed or irrigated.

In obstetric cases the method is said to be of especial value, nervous patients lying quietly and comfortably in some cases for as long as one or two hours during the painful second stage of labor, neither at the time nor afterwards having any appreciation of the pain of childbirth. It is further recommended for examinations, the same perfect relaxation being obtained as under general anesthesia, while at the same time the patient can aid the examiner by deep breathing and voluntary movements. It is said to be of distinct value in conjunction with lumbar anesthesia, relieving the patient of all mental anxiety, and in the early stages of a general anesthetic.

CYCLIC VOMITING.

There are few diseases of childhood the etiology of which has been the subject of more divergent opinions than the periodic occurrence of vomiting which for want of a better title is known as cyclic vomiting. Thought at first to be purely of neurotic origin, the discovery of acetone in the breath and urine caused the disease to be classed as an acidosis, and to be treated by the administration of large doses of alkalis. A wider knowledge of the physiology of the presence of acetone and diacetic acid in the urine, however, demonstrated that these substances might appear in a child with protracted vomiting from any cause, and even in other conditions in which deprivation of food caused a certain degree of starvation, without the accompanying emesis. The acidosis and acetonuria was therefore accepted as a result rather than a cause of the cylic vomiting. Langmead of London considered the condition to be caused by an intestinal intoxication with absorption of a fat splitting poison, which resulted in the tissues being flooded with acetone and the other products of fat catabolism. Comby, on the other hand, has presented the theory that the symptom complex was in reality a manifestation of chronic appendicitis. In the *British Journal of Children's Diseases* for February, 1910, Russell reports a case of cyclic vomiting which is in many ways suggestive of at least a possible cause of the condition. The patient, a boy of four years and nine months of age, had suffered from periodic attacks of vomiting from birth, each attack lasting in the neighborhood of twenty-four hours. His final attack was more prolonged and was interrupted by a remission. The first part lasted one week and was characterized by frequent vomiting, rapid emaciation, and the presence of acetone and diacetic acid in the urine. This stopped as abruptly as it began, but after three weeks of apparently good health it recurred, and at the end of five days the child succumbed. The au-

topsy showed a marked degree of hypertrophy and stenosis of the pylorus. The author, while not claiming that such a hypertrophic stenosis of the pylorus is the usual, or even a common, cause of cyclic vomiting, calls attention to it as a possible etiological factor of this puzzling disease. Recurring spasm of a hypertrophied pylorus would at least explain the symptomatology of cyclic vomiting, its sudden onset with the beginning of the spasm, and its equally prompt relief with its cessation. The condition of the pyloric valve should at least be considered and investigated in these cases of periodic vomiting of childhood.

News of the Week.

A Proposed Investigation of Physiological and Surgical Laboratories.—A bill has been introduced in the New York Assembly by Mr. Goodspeed, "To establish a commission to inquire into the extent and nature of the practice in this State, of experimentaion on living animals, together with the condition of the laws of the State relative to the proper protection of scientific experiments without danger of unnecessary cruelty." The act provides that, "The Governor is hereby authorized to appoint a commission which shall consist of seven members, two of whom shall be physicians or scientific men residing in this State, two of whom shall be active members of some organization of this State, having for its purpose the prevention of unnecessary cruelty in vivisection, two of whom shall be lawyers practising within this State, and the remaining member of the commission shall be appointed at large. The commission shall choose a member thereof as chairman. Such commission shall serve without compensation, and shall make inquiry, examination, and investigation into the practice of vivisection or experimentation on living animals in this State. It shall also make a full inquiry and investigation into the condition of the law for the protection of scientific investigation of this character in this State, as well as the condition and effectiveness thereof for the prevention of abuse in vivisection and of unnecessary cruelty to animals therein. For these purposes the said commission is hereby authorized to send for persons or papers, to administer oaths, and to examine witnesses and papers respecting all matters pertaining to this subject. Such commission may employ necessary clerical or other assistants, and shall make a full and final report to the Governor within one year after its appointment, including such recommendations for legislation as in its judgment may seem proper." The same bill was introduced in the Senate by Mr. Bayne.

The Committee on Prevention of Tuberculosis of the State Charities Aid Association held a two days' conference in Albany, March 18 and 19. The topic of discussion at the first session was "Discovery and Supervision of Cases in the Home." At the banquet in the evening the subject was open-air schools not only for tuberculous children but for all children. The discussion the second morning was upon the institutional care of tuberculosis as the best means of prevention and cure. The conference closed with a mass meeting at which, among others, President Taft and Governor Hughes were speakers.

Plague in Hawaii.—Rear-Admiral Corwin P. Rees, commandant of the Naval Station at Honolulu, has advised the Navy Department of the existence of plague in the islands. Four deaths have occurred on the Island of Hawaii—two in Hilo, two in Honokaa. There are no suspicious cases on any other island.

To Study Pellagra.—The United States Public Health and Marine Hospital Service has ordered Past-Assistant Surgeon C. H. Lavinder to Milan, Italy, to make a study of Pellagra in that neighborhood.

The Lakewood Preventorium. — Supreme Court Justice Gerard of New Jersey has denied the application by Mr. Nathan Straus for an injunction restraining Mr. Nathan and the Lakewood Hotel Company from ejecting the tuberculosis preventorium from the Cleveland cottage in Lakewood. This necessitates the preventorium leaving Lakewood.

Medical Schools to Consolidate.—An effort is being made in Oklahoma to bring about the consolidation of the Oklahoma State University and the Epworth Medical College to enable the third and fourth year students of the two institutions to obtain their instruction together, the new rule to be effective the next school year. The plan, which has been under consideration for weeks, has been approved by Governor Haskell, deans of the medical departments of Epworth and the State university and the board of regents of the university. The only obstacle now is whether the State law, which says the University of Oklahoma must be located at Norman, stands in the way of the consolidation.

Contagious Hospital for Cambridge, Mass.—Appropriation has been voted by the City of Cambridge of the sum of $95,000 for the construction of a new hospital for contagious diseases.

Charitable Bequests.—By the will of the late Elizabeth Hopple of Philadelphia provision is made for the sale of the testatrix's jewelry for the establishment of a free bed in the children's ward of the Presbyterian Hospital at a cost, however, not exceeding $3,000. By the will of the late Charles E. Etting of Philadelphia the sum of $10,000 is bequeathed to the Philadelphia Orthopedic Hospital and Infirmary of Nervous Diseases, for the endowment of two perpetual free beds. By the will of the late Jacob Steinmetz Thorn of Philadelphia, disposing of an estate exceeding $200,000, the sum of $5,000 is bequeathed to the Episcopal Hospital for the endowment of a free bed in the memory of his widow, Florence E. Thorn. Upon the death of the widow the principal of the residuary estate is to be divided among several institutions, including the Home for Incurables, the Medico-Chirurgical Hospital, the Pennsylvania Hospital, and the Sanitarium Association.

Dr. J. Solis-Cohen.—A testimonial dinner was given to J. Solis-Cohen of Philadelphia, on March 15, by former assistants and associates, in celebration of the fiftieth anniversary of his graduation from the medical department of the University of Pennsylvania.

Dr. A. C. Abbott has been appointed by Dr. Joseph Neff, Director of Public Health and Charities, Philadelphia, delegate to the International Congress of Hygiene and Medicine to be held at Buenos Ayres, Argentine Republic, in April. He will make an exhibit of medical inspection of schools.

The Florida Medical Association will hold its thirty-seventh annual meeting at Jacksonville, April 6, 7, and 8, 1910. The *President* of the Association

is Dr. H. E. Palmer of Tallahassee, the *Secretary and Treasurer* is Dr. J. D. Fernandez of Jacksonville, and the *Chairman of the Committee of Arrangements* is Dr. P. C. Perry.

The Harvey Society.—The eighth lecture of the Harvey Society will be delivered by Professor Magnus-Levy of the University of Berlin at the Academy of Medicine, New York, on April 9 (not on April 2 as previously announced), at 8.30 P.M. The subject will be "Pathology and Therapy in Diseases of Metabolism." All those interested are cordially invited to be present.

Association of American Medical Colleges.—At the annual session of this Association, held in Baltimore this week, the following officers were elected: *President,* Dr. J. A. Witherspoon, Vanderbilt University; *First Vice-President,* Dr. H. D. Arnold, Tufts College; *Second Vice-President,* Dr. Charles R. Bardeen, University of Wisconsin, and *Secretary-Treasurer,* Dr. Frederick C. Zapffe, University of Illinois.

The City Hospital of Providence.—The consulting staff of the new City Hospital of Providence, R. I., has been appointed as follows: *Medicine*—Drs. Frank L. Day, Edmund D. Chesebro, William Gleason and Joseph M. Bennett. *Surgery*—Drs. Edgar B. Smith and John W. Keefe. *Ear, Nose, and Throat*—Drs. Edward S. Bacon and N. Darrell Harvey. *Eye*—Drs. Frederick T. Rogers and George Van Benschoten. *Dermatology*—Drs. Gardner T. Swarts, Harry W. Kimball, and J. T. Farrell. *Pathology*—Dr. Frank T. Fulton.

Obituary Notes.—Dr. ALFRED A. STOCKER of Cambridge, Mass., died at his home, March 15, 1910, aged 90 years. Dr. Stocker was a graduate of the Harvard Medical School in 1853. During the Civil War he attained prominence as a military surgeon, having served as major-surgeon to several regiments.

Dr. MARTIN AMADOR of Brooklyn died at his home, March 13, 1910, aged 52 years. Dr. Amador belonged to a family prominent in South American affairs, his father having been President of Colombia and his cousin of Panama. He was born in Cienago de Oro, Colombia, and coming to the United States in his youth was graduated in 1878 from the medical department of the University of New York. After serving for some time as an assistant in the City Hospital on Blackwell's Island he was called as professor of anatomy, physiology, and surgery to the University of Cartagena. Later he was Consul-General of Colombia in Holland and Belgium and afterward was Vice-Consul of the United States in Colombia. He settled in Brooklyn in 1893. He was a member of the Kings County Medical Society, the Associated Physicians of Long Island, and the Medical Society of the State of New York.

Dr. DANIEL EDMUND BARRY of New York died at his home, March 13, 1910, aged 59 years. He was a graduate of Trinity College, Dublin, and of the College of Physicians and Surgeons of New York in 1874. He was a member of the Medical Societies of the County and State of New York, and of the American Medical Association.

Dr. WILLIAM WILLET MOON of Brooklyn died March 13, 1910, aged 40 years. Dr. Moon was a graduate of the University of Virginia, in 1892, and a member of the Homeopathic Medical Society of King's County.

Dr. THOMAS J. BRODERICK of Charlestown, Mass., died at his home, March 5, 1910. He was a graduate of the Harvard Medical School in 1882, and was a member of the Suffolk County Medical Society and the Massachusetts Medical Society.

Dr. EDWARD C. CRUM of Dayton, O., died at his home, March 4, 1910, aged 63 years. Dr. Crum was a graduate of the Miami Medical College in 1870, and was a member of the Montgomery County Medical Society and the Ohio State Medical Association.

Dr. WILLIAM E. DEMPSEY of Fayetteville, W. Va., died at Deland, Fla., March 1, 1910, aged 37 years. He was a graduate of the University of Louisville in 1897, and was a member of the West Virginia State Medical Association and the American Medical Association.

Dr. ROBERT GEORGE ENGLISH, formerly of Des Moines, Ia., died at the home of his daughter, in Osawatomie, Kan., March 4, 1910, aged 92 years. Dr. English was a graduate of the Northwestern University and one of the pioneer physicians of Kansas.

Dr. FREDERICK S. GRAY of Troy, Vt., died at his home, March 10, 1910, aged 53 years. He was a graduate of the University of Vermont, in 1882, and a member of the Orleans County Medical Society, the Vermont State Medical Society, and the American Medical Association.

Dr. ANDREW W. HORTON of Pelham, Ala., died in Atlanta, March 4, 1910. He was a graduate of the Medical College of Alabama in 1899.

Dr. U. S. INGRAM of Pineville, Ky., died in Louisville, March 11, 1910, aged 35 years. He was a graduate of the Hospital College of Medicine in Louisville in 1898.

Dr. WILLIAM F. KNAPP of Monroe, Mich., died on March 10, 1910, aged 55 years. He was a graduate of the University of Michigan in 1878.

Dr. JULES LAZARD of New Orleans died March 4, 1910, aged 34 years. Dr. Lazard was a graduate of the Medical Department of Tulane University, in 1898. He was professor of physiology in the New Orleans College of Pharmacy, visiting surgeon of the Charity Hospital and Touro Infirmary, and consulting surgeon of the Presbyterian Hospital. Formerly he was treasurer of both the New Orleans Medical Society and the Louisiana State Medical Society, and served as statistical officer for the U. S. Marine Hospital Service during the yellow fever epidemic of several years ago.

Dr. JOHN N. MATTHEWS of Mason, Ill., died at his home, March 8, 1910, aged 58 years. He was a graduate of the Missouri Medical College, in 1878, and a member of the Effingham County Medical Society and the Illinois State Medical Society. Dr. Matthews was also well known for his literary attainments as a magazine writer and poet.

Dr. WALTER J. SMITH of Providence, R. I., died at his home, March 13, 1910, aged 53 years. He was a graduate of the Yale Medical School in 1878.

Obituary.

WHARTON SINKLER, M.D.

PHILADELPHIA.

WITH the death in Philadelphia, on March 16, 1910, of Dr. Wharton Sinkler, not only that city but the country has lost one of its leading physicians. Dr. Sinkler who died at the age of 65 years from angina pectoris had for many years been one of the prominent figures in American medicine. He was graduated from the medical department of the University of Pennsylvania in the class of 1868. He

was Physician to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, Neurologist to the Bryn Mawr Hospital, Consulting Neurologist to the State Hospital for the Chronic Insane at South Mountain, President of the Board of Managers of the Pennsylvania Colony Farm for Epileptics, Manager of the Episcopal Hospital, Consulting Neurologist to the Widener Home for Crippled Children, Trustee of the University of Pennsylvania, Neurologist to the Germantown Hospital, Trustee of the Eastern Pennsylvania Institution for the Feeble-minded and Epileptic, President of the Alumni Society of the Medical Department of the University of Pennsylvania, Vice-president of the College of Physicians of Philadelphia. He had been President of the Philadelphia Medical Club, Neurologist to the Philadelphia Hospital, Physician to the Episcopal Hospital, Chairman of the Section of Neurology of the American Medical Association, President of the Philadelphia Neurological Society, and President of the American Neurological Association. He was a member of many medical, social, and secret organizations, and a liberal contributor to medical literature. He described the toe-jerk and he pointed out the prevalence of acute anterior poliomyelitis in the spring of the year.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING EDWARD'S HOSPITAL FUND—LATENT APPENDICITIS—EFFECTS OF CALCIUM ON THE BLOOD—TROPICAL RESEARCH—BEIT FELLOWSHIPS—SIMPSON'S LECTURES—HANDLEY ON LYMPHATIC SYSTEM—CANCER HOSPITAL—PELLAGRA—LADY PRIESTLEY LECTURESHIP—OBITUARY.

LONDON, March 3, 1910.

THE annual meeting of the President and General Council of King Edward's Hospital Fund was held yesterday at Marlborough House. The Prince of Wales, as president, occupied the chair, and the honorary treasurer, Lord Rothschild, presented the statement of accounts for the year ending December 31, 1909. The report of the council was also presented, and in moving its adoption the Prince congratulated themselves on the total sum distributed since the foundation of the fund, thirteen years ago, being more than £1,000,000. His Royal Highness also referred to the satisfactory list of legacies received during the year, amounting to £46,400, not including £75,000 from the estate of the late Samuel Lewis, from which latter source the fund has benefited to the extent of £328,000. With reference to the proposed committee of inquiry into the system prevailing in London voluntary hospitals with regard to the admission of out-patients, His Royal Highness hoped that it may be appointed during this year and commence its work at the beginning of 1911. The Duke of Norfolk seconded the report, which was carried, remarking that the fund had now reached a point which His Majesty had in his mind and heart when he first promoted it.

For several weeks a favorite topic of conversation when doctors meet has been latent appendicitis, or, as some now call it, "appendix dyspepsia." It is not a new subject to many of us. Your surgeons are pretty well acquainted with it, and for the last nine or ten years one has heard of it from Germany. Opinions here are divided, so discussion has been pretty free. I reported to you the debate on ulcer of the duodenum, and this seems to follow naturally, for, among other difficulties attending appendicular disease, gastric and duodenal symptoms of all sorts are attributed to it. Mr. Moynihan, whose experience I gave you in a former letter, holds that what he calls "appendix dyspepsia" is far more common than has been believed, far more than he himself supposed until his operative work forced the conclusion upon him. He has found all the symptoms of ulceration of the stomach and duodenum, acute and chronic, including even hemorrhages in cases which, on operation, revealed no trace of such a lesion, but in which he found a diseased appendix and removed it, the result being a complete cure. He now considers that, if on operation no ulcer is found in the stomach or duodenum, it is not right to do a gastroenterostomy until examination has been made of the appendix, and indeed of the small intestine and mesenteric glands. It certainly seems reasonable that when the abdomen has been opened in consequence of an erroneous diagnosis it should be as thoroughly searched for unsuspected lesions as the state of the patient permits. It is not only when the symptoms have been so severe as to induce the patient to submit to operation and so indicative of ulceration as to compel the physician to hand over the treatment to the surgeon, but in quite a number of other cases of pain, vomiting, diarrhea, colic, and so on, which are termed dyspepsia, or perhaps colitis or gallstones, or bilious attacks, on account of the difficulty of being certain as to the precise lesion. In all such an exploratory operation may reveal the exact organic lesion, and the modern surgeon will know how to proceed. But many a medical attendant will be asking whether all these symptoms may not, as he has been taught, be due to functional disorder. Even surgeons will admit the possibility of this and the possible danger of unnecessary operations being performed as the result of wide surgical experience attracting to skilled operators an undue proportion of troublesome cases.

Mr. Bowlby takes the cautious view, and has written a letter expressing a fear that many dyspeptics may be submitted to excision of the appendix and that the "majority may be none the better." His great authority as a surgeon is reinforced in this case by the fact that he has long had his attention diverted to the danger that the inexperienced might mistake stomach attacks for appendicitis. He spoke of this in a clinical lecture published in the *Lancet*, June 9, 1904, and, as he has now restated his views, he has become, as it were, the leader of the opposition to those of Mr. Moynihan. For there is a decided division of opinion among practitioners, even those who have no direct experience to contribute, and the hesitating ones are, I think, in the majority. This is to be expected, for physicians and text books have long been impressing on students the variability of digestive derangements and the indirect and distant symptoms to which they often give rise. Mr. Moynihan speaks of hematemesis as occurring in appendicitis; but this must be very unusual, for none of the writers on the subject mention it, and I have not heard any one say he has met with it. As to simple vomiting, it occurs in so many different conditions that one instinctively asks for other indications. Its cause may be in the stomach, and either functional and of little consequence or organic and of grave import. So it may be indirect or reflex and organic, either of slight or very great importance. It is easy, therefore, to understand the fear that unnecessary operations may be performed, and, on the other hand, the regret that necessary ones have been delayed too long. These different views in some degree are characteristic of two branches of the profession—the operating surgeon sees a considerable proportion of rare or difficult surgical cases; the family doctor finds the average of such quite insignificant in numbers. So it was the surgeons who showed the nature and frequency of appendicitis, which, until this generation, passed under other names. This being so, the existence of latent appendicitis seems no more improbable than various other conditions.

With regard to the permanency of the cure by operation, very positive statements have been made, and they seemed so natural that they have hardly been questioned. If symptoms returned the diagnosis had been erroneous. But cases have occurred in which, after the removal of a diseased appendix, the symptoms have continued or shortly returned. Obviously, the lesion of the appendix was not the sole cause. An apt illustration has just been recorded. Prof. C. A. Ewald wrote to the *British Medical Journal* an account of a case in which the operator found the appendix thickened, inflamed, and adherent to the colon and ovary, adding "the complaints never returned." This only means he had not been further consulted, for Dr. E. A. Roberts writes to say that he feels it his duty to state that "she still suffers from all her old symptoms." Further, the patient assures him that "the operation was not followed by any alleviation of her troubles." Clearly, in this case the appendix was not the root of all the mischief.

The effect of calcium salts on the blood is not so simple as some of our therapeutists have declared. Prof. B. J. Collingwood has lately been experimenting on the in-

fluence of these salts on the blood *in vitro*, and has told the Dublin Academy that the rate at which the blood is shed makes a great difference in the time required for coagulation. None of his experiments gave any evidence that the addition of calcium increased the coagulability. In fact, an amount sufficient to appreciably increase the calcium content of the blood rather diminished the coagulability. From this it would seem that the therapeutical value attributed to these salts depends on other factors than the amount of calcium in the blood. The experiments were carried out at Sir A. Wright's laboratory at St. Mary's Hospital. In a number of trials on himself Professor Collingwood had not found that he could absorb any calcium. He thought that the clinical results reported might depend on vasoconstriction and that injection of serum would be a more rational treatment for the prevention of hemorrhages, but serum differed much according to the time which had elapsed after withdrawal.

Professor Milroy said blood taken by a cannula would not clot for a certain time, but a particle of tissue would cause it to do so at once, so that a drop squeezed from the finger might be influenced by contamination. Professor McWeeney referred to the statement that milk diet increased the calcium, and to this had been attributed the frequency of thrombosis in convalescence from typhoid. Mr. Wheeler said it was usual to give large doses a few days before prostatectomy, but could the medicine retain hemostatic power for days? He believed Moynihan discredited the treatment and adopted an alien serum. In reply, Dr. Collingwood said milk contained other constituents. In typhoid the feebleness of circulation might be a factor. As to continuity of action calcium had been considered by many as a physiological cardiac stimulant.

In the report for 1909 of the advisory committee for the Tropical Diseases Research Fund the revenue is stated as £3,470, of which £1,000 was contributed by the British Government, £500 by that of India, £200 by the Rhodes Trustees, and £1,770 by several Colonial governments. As the five years for which the grants were made is about to expire, the Secretary of State has asked the opinion of the advisory committee as to a renewal. The committee replied most emphatically that the work done had been of the highest value, and it would be a calamity if it were restricted. The Governments concerned have accordingly undertaken to continue their grants for another period of five years.

The trustees of the Beit Memorial Fellowships for Medical Research have elected the first ten Fellows; the appointments date from March 1, and are tenable for three years, the remuneration being £250 per annum. Candidates must be of European descent and must have taken a degree in some British university approved by the trustees. There are no restrictions as to age or medical or religious opinions. The ten Fellows now elected are: Drs. George H. Drew, F. W. Edridge-Green, Edward Hindle, Thomas Lewis, G. C. M. Mathison, Otto May, Edward Mellanby, Fred. P. F. Ransom, Sidney Russ, and Ida Smedley. The subjects adopted for the researches include "Cancer and Neoplasms," "Vision and Color Vision," "Protozaic Blood Parasites," "Mechanism and Irregularities of the Heart," "Nervous Control of Respiration and Effect on It of Blood Changes," "Mechanism of Biliary Secretion and Its Effect on Digestion," "Lesions of Peripheral Nerves," "Excretion of Creatine in Relation to Cancer and Cirrhosis of Liver," "Action of Caffeine Theobromine and Allied Substances on the Muscular and Nervous Systems," "Association of Radioactivity with Cancer and Formation of Fat in the Organism."

The next election of ten Fellows will be about the 15th of December, and the apointments then made date from January 1 of next year. Applications must be sent in before the 15th of November.

Professor Simpson's lectures at the Chamber of Commerce, which I mentioned a fortnight ago, were brought to a conclusion yesterday with one on "Bacteria." The course has not been so well attended by merchants and members of the chamber as was hoped, but a good beginning has been made in spreading an interest among them respecting tropical diseases and hygiene.

Mr. F. Swanzy, chairman of the West African Section of the Chamber, in moving a vote of thanks, spoke of the good work done by the London and Liverpool Schools of Tropical Medicine, and said a further appeal would be made to the city, perhaps at the Mansion House, for funds needed and well deserved. Mr. Batty seconded and supported this appeal, specially emphasizing the research work of the London school. The professor briefly replied to the vote, which was unanimously carried.

Prof. Sampson Handley of the Middlesex Hospital Cancer Research Laboratory, lecturing at the Royal College of Surgeons on the "Surgery of the Lymphatic System," remarked that the subject had been rather neglected, but was of great importance. He expressed the opinion that cancer, being a disease which mainly spreads through the lymphatic vessels, might be looked upon as a branch of the surgery of the lymphatics. He gave an account of his method of burying silk threads in the tissues to replace lymphatics which had been destroyed in the course of cancer. The swollen arm, which is so painful and frequent complication of mammary cancer, treated by his method, he said, was usually successful, unless subsequent effusion interfered with the drainage, the relief generally continuing for the rest of the patient's life.

At the annual meeting of the Cancer Hospital, the president, Lord Northbrook, announced that it had been decided to change the name of the Research and Pathological Department to the "Cancer Hospital Research Institute," and to enlarge it by erecting on a site adjoining the hospital grounds a building where laboratories and every facility will be provided for investigating the disease in every direction. The committee felt it a duty to join in the campaign against this deadly foe of the race now being so earnestly carried on. He hoped and even believed that eventually success would be attained and cancer be brought into the class of controllable diseases. The financial position, the president pronounced satisfactory, compared with previous years. The report was adopted.

The Pellagra Committee is succeeding. To assist Dr. Sambon on the field it has appointed Captain Siler, who has worked on the subject on your side and recently at the London Tropical School; Mr. Baldwin, a St. Bartholomew's student, and Mr. Dawson-Amoroso, microscopist. The two latter gentlemen are Italians and their knowledge of the language and the pallagrous areas in Italy will be of considerable assistance.

The National Health Society proposes to establish a "Lady Priestley Lectureship" in memory of the lady who has done so much for the society ever since it started, some thirty years ago.

Prof. John W. Taylor, F.R.C.S., M.D., M.Sc., died on the 26th of February, aged 59. He was senior surgeon to the Birmingham and Midland Hospital for Women and professor of gynecology in the University of Birmingham, president of the Midland Medical Society, 1897-1898, and vice-president of the British Gynecological Society, 1894. He delivered the Ingleby lectures in 1898 on "Extrauterine Pregnancy," which he embodied in his work on that subject. He translated (jointly with Dr. Edge) Dührssen's Manuals, and contributed freely to the journals and societies. The late professor was a musician of well-marked ability and was possessed of other artistic and literary tastes. His health had failed for the last year or more and for longer still he had had cardiac trouble.

The death is announced of Inspector-General R. S. P. Griffith at the age of 65. He joined the Naval Medical Service in 1867. He was staff surgeon of the Orontes in the Egyptian War, 1882, and received the medal and the Khedive's bronze star. He became Inspector-General of Hospitals and Fleets in 1901 and retired in 1904.

Surgeon-Major-General G. L. Hinde, A.M.S., has died, aged 77. He was L.R.C.P.I., 1855, in which year he entered the army as assistant surgeon. He served in the Crimea and received the medal with clasp. In 1884-1885 he was in the Soudan campaign, obtaining mention in dispatches, the medal with clasp, and the Khedive's star. He was also awarded a C.B. He retired in 1892.

Associated Medical Libraries of Berlin.—It is proposed to unite all of the medical libraries in the city of Berlin into one organization under the above title, of which Professor E. A. Ewald will be the president. The association if formed will include the library of the Berlin Medical Society, of the German Surgical Society, of the Dermatological, Laryngological, Otological, and Roentgenological Societies, of the Imperial Committee for the Study of Cancer, and of the Medical Department of the Empress Frederick Foundation.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 10, 1910.

The Uses of Fear in Preventive Medicine.—M. J. Rosenau is of the opinion that the sum total of fear has greatly diminished with the progress of the world, but that while it is lessoning one would not want it to disappear entirely, for it has its uses in the same sense that pain may be a marked benefit to the animal economy and in the same sense that fever is a conservative process. Reasonable fear saves many lives and prevents much sickness. It is often the fear of a disease that gives the health officer the ways and means to combat it. The fear of cholera is so great that it is never permitted to get a foothold in the country. If there was a corresponding fear of typhoid fever we would soon see it diminish to the vanishing point. Fear has been a great aid in checking epidemics, in urging on the fight against tuberculosis. To get the greatest benefit from fear it must be directed into the proper channels. For instance, when the fear of yellow fever is transformed into fear of the mosquito there will be no more yellow fever in our seaports. While fear has its uses, it may be overdone. The fact that germs are invisible magnifies the supposed danger until extremists suspect that death lurks in every particle of air, food, and dust. Such a fear of danger must be regarded as an indication of an unstable and nervous temperament and must be regarded as pathological. The final conquest will come when the blind fear of disease itself has given place to an enlightened appreciation of the dangers. This is the fear that preventive medicine uses.

Submucous Fibroids.—Philemon E. Truesdale summarizes his paper on this subject as follows: 1. The submucous fibroid, clinically, may be considered a malignant growth. 2. It commonly occurs with one or both of the submural and subserous types, and is then easily diagnosticated. 3. It occurs alone with relative infrequency and is then usually not discovered until late. 4. Hemorrhage at the menstrual periods and between the periods, frequently with dysmenorrhea, characterizes its presence. 5. When it is of large size and sessile, hysterectomy is the operation of safety. In certain cases the choice of the operation may be left with the patient. The comparative risks of the operations and the possibility of malignant degeneration of the tumor should be clearly presented to the patient.

Periodical Hemoptysis.—Theodore J. Eastman finds, in going over the literature, that there are a certain number of women in whom there is a definite pulmonary hyperemia before and during menstruation. During this period the capillaries and larger vessels of the lungs are more engorged with blood than under ordinary conditions and are more liable to rupture. Pulmonary hemorrhage in the clinically sound person is very rarely fatal, and is of very little importance aside from the incident of fright. In the tuberculous person, however, it is of great importance. It is important that women with pulmonary tuberculosis should be more than ordinarily quiet during the few days preceding and during the menstrual period, particularly if they have ever had any hemoptysis. If it is found that hemorrhages tend to recur at intervals corresponding to the menstrual periods, it is wise to keep the patient in bed during the time above mentioned. Percussion and forced breathing should be carefully avoided during this period and no physical examination made except perhaps auscultation of the whispered voice.

New York Medical Journal, March 12, 1910.

Dementia Præcox.—In discussing dementia præcox and its allied states Smith Ely Jelliffe calls attention to the etymological significance of the words. It means not that dementia should occur in a young individual, but that it was characteristic of this group of mental disorders that a certain grade of mental enfeeblement should come early in the affection. He then gives a historical summary of dementia præcox He has thus far found no passable description of precox types in the classical Greek writings, though there is no doubt that this type of deterioration was then present and recognized and grouped for the most part under the large heading of melancholia. Willis, the English anatomist, in 1672 clearly portrayed the condition, though this type of cases was arranged under the general terms stupiditas, idiocy, and imbecilitas. The works of authors of the seventeenth century are replete with classical examples. In the work of Sauvage, published in 1772, one finds an excellent description of "catatonic negativism." It appears that with the ancients a single general process is apportioned off into several pigeon holes and in its various phases is diagnosed as different disorders. In 1809 Pinel reduces the innumerable varieties of mental disorders of Sauvage and others to four forms. Later he added a fifth division and it is certain from his writings that neither Pinel nor his great follower, Esquirol, could fail to recognize most cases of what are now called dementia præcox, and one finds excellent examples of this affection in Pinel's five classifications. Some of his best illustrations are found in his chapter on idiocy. He speaks of idiocy as being the most frequent form of disease in the hospital, just as we now know dementia præcox to be. Benjamin Rush probably included dementia præcox in his groups of manalgia and of demence, or dissociation. It is not a sign of modern acumen to say that psychiatry has made no advances, for it has made as rapid strides through the centuries as other branches of medicine. In France, during the eighteenth and nineteneth centuries, Corry, Camus, Tissot, Armand, Pinel, Esquirol, Guislan, Bayle, Baillarger, and Falret were working, and in Germany Erhard, Hoffbauer, Reil, Horn, Heinroth, Jacobi, Ideler, Friedreich, Nasse, Damerow, Feuchtersleben, Greisinger, and Flemming occupied the contemporaneous stage. In England there were Cullen, Arnold, Crichton, Perfect, Harper, Pargeter, Haslam, Cox, and Marshall. There was evidence to show that every one of these writers had seen cases of dementia præcox and that the most conservative would regard them under at least four heads, while in others one could read their symptoms in at least fifty different places. It was time to introduce some coordination and this work was begun by Bayle in 1828 under the head of chronic arachnitis. The more recent history of dementia præcox concerns itself with the work of Kahlbaum, Hecker, Pick, Dareazkiewicz, and Kraeplin. The present day division of dementia præcox usually includes three fairly marked types, the hebephrenic, the catatonic, and the paranoid. Each of these has a history. It took a period of thirty-five years to bring about a synthesis of this group under the heading of dementia præcox. The writer carefully traces out the evolution of this classification.

Brain Storm.—Frank Woodbury says that "brain storm" is a phrase familiarly used to describe brief states of mental emotional perturbation without reference to their cause. It is a popular and not a scientific term. Such attacks may be induced by atmospheric and climatic conditions to an extent not usually known or suspected. The presumed proximate causes in such cases are only incidental. The real causes lie deeper. Emotional and confusional conditions may occur in apparently normal persons, but are met with more frequently among the insane. The so-called brain storms will be observed most frequently in persons who are neurasthenic and in a depressed vital condition. They are frequently epileptic or epileptiform. They usually indicate a pathological condition of the body or mind. Violent outbursts of rage or emotion have medical importance and when they are of frequent occurrence should be investigated by a physician skilled in mental disorders. The phrase brain storm in medicolegal cases is popularly understood to imply a temporary loss of will power and a diminished responsibility on the part of the individual, which is the very point at issue when the case is brought before the court. The use of figurative and unscientific language by medical witnesses is objectionable since it tends to influence the minds of the jury unduly in weighing the culpability of the prisoner under trial. Under penalty of being suspected of willingness to "darken counsel by words without wisdom" alienists and other medical experts should avoid ambiguous and unscientific terms of this character and should discourage, both in publications and discussions, the use of the term "brain storm."

The Abstraction of Calcium Salts from the Mother by the Fetus the Cause of Fatty Infiltration of the Liver Cells of the Former.—Jennie G. Drennan in two former articles attempts to prove in a case of scarcity of the calcium salts in the mother's blood during pregnancy the fetus may so drain it of these salts that her tissues suffer. During pregnancy and lactation the liver cells surrounding the hepatic vein become infiltrated with fat; this she does not consider to be

physiological, but rather that the condition arises from the fact that the calcium salts which should be available for combination with this fat are being drained off by the fetus and the mother's tissues are suffering from a lack of these.

Tuberculous Ulcers of the Stomach.—The infrequency of this condition is the reason for a brief report of two cases by A. G. Ellis. Both cases were secondary to well-marked lesions elsewhere, and illustrated two types of extension of the tuberculous process to that organ. The first was evidently due to ingestion of bacilli derived from the pulmonary lesion, the second to extension of the process from the contiguous peritoneum.

Journal of the American Medical Association, March 12, 1910.

Survival of Ingrafted Tissues.—C. C. Guthrie has experimented by grafting one entire thyroid lobe in a young dog, with reversal of the circulation, with apparent success, though the operation created considerable disturbance. He thinks that, considering the circumstances, the autoingrafted tissue being perfused with saline solution, its circulation reversed, and the wound infected, all these conditions being unfavorable, still better results will be obtained under better conditions. The results on the parathyroid have not yet been sufficiently studied. It is sufficient to say that the survival of an exceedingly small portion of ingrafted parathyroid tissue seems adequate to prevent the appearance of tetany, etc. The parathyroid tissue would seem to be the most precious of any in the body of which we have specific knowledge. Ingrafting of the whole kidney with anastomosis of the blood vessels was performed in other experiments and the general results are summarized as follows: "Renal isografts with anastomosis of blood vessels and ureters have so far been only temporarily successful functionally, as shown by the death of the animal within a few weeks. Anatomically, congestive, hemorrhagic, and degenerative changes occur so that the normal structure is soon lost. After a year, when sufficient renal tissue was left to perform the required physiological functions, the transplanted kidney still presented a reminiscence of renal structure, but was totally incapable of adequate functioning, as shown by the death of the animal (cat) on the removal of the original normal kidney." The experiments on the transplantation of the adrenals have not been sufficiently studied to admit of conclusions, and the results of a series of experiments on the thyroid and renal apparatus of fowls will be given later. The article is illustrated.

Syphilis and the Negro.—G. W. Murreli points out the disadvantages of the lack of vital statistics of the negro of the south as leading to a misunderstanding of southern conditions. He makes a comparison of the negro of 1859 and the negro of 1909, especially in the matter of sexual disease, greatly to the disadvantage of the latter, and says that disease and dissipation have done their work only too well. Insanity has increased over 1,000 per cent. in fifty years. The high birth-rate immediately following the emancipation has decreased to barely one-fourth of what it was. Morality is very low, and specific diseases have consequently increased and become almost universal. The present degenerate negro dies faster and has fewer children than his ancestors. It is his honest belief, Murrell says, that in another 50 years we will find an uninfected negro a freak. Religion does not seem to help the negro, as he has altered the decalogue to suit his conditions. Murrell considers syphilis a far more common scourge than tuberculosis and the subjects of one have often to combat the other also. The disease, he says, is most severe in its manifestations in the negro and his hygienic habits are as bad as can be. There is a special tendency to the papular-serpiginiform formations around the mucous outlets. On account of the almost invariable only partial treatment there is a great predominance of relapsing syphilids. Mucous patches are not so common, on account of the better average teeth of the negro. Murrell claims that serum treatment in some form is the only hope of eradicating the disease from the race and it would have to be compulsory. In treating the negro, one must do nothing to give him pain, such as hyperdermic injections, nor will he do anything so troublesome as the application of inunctions. With him it is treatment by the mouth or nothing. The disease, he thinks, is a social menace and the future of the negro lies more in the research laboratory than in the schools. Murrell sees no good in his citizenship. He needs a paternal government. Fifty years more, he thinks, will give us another type, more puzzling than those we have now and a still more serious problem.

Nitroglycerin Head.—C. E. Laws describes the symptoms of nitroglycerin poisoning as observed in dynamite factories, etc. Effects are liable to be produced by even slight contacts with clothing, etc., of the workers, in susceptible individuals. The headache is the most distressing. Some persons seem to be immune. All workers in the substance experience some inconveniencs, dyspnea, tachycardia, and genitourinary disturbances, but it does not seem seriously to affect the general health in those habituated. Treatment is generally unsatisfactory in the severe cases and acquired immunity is soon lost.

The Urine in Diabetes.—W. Lintz says that the urinary findings in diabetes not only give the diagnosis of the disease but throw light on the etiology and aid the surgeon and physician when their work is complicated with diabetes. Certain mistakes, however, must be avoided. The sugar test may fail unless a twenty-four-hour sample is taken and it may disappear and be replaced by uric acid and phosphates. The turbidity of diabetic urine is noticeable and it is of practical importance as it is due to the growth of yeast cells which may cause, by fermentation, complete disappearance of glucose if the qualitative and quantitative examination is not made sufficiently early. Many other substances than glucose will reduce the various copper solutions, among which may be mentioned as most frequent, conjugated glycuronic acid, alkapton, creatinin, uric acid in excess, blood, and lactose. A point that he had not seen mentioned elsewhere is that occasionally the urine of menstruating women will reduce the copper solution, on account, as he is fully convinced, of the presence of blood in the urine. This is an important point. Blocking of the secretion of the mammary glands may also produce lactose in the urine and the fermentation test will reveal the difference. It is surprising, Lintz says, how easy it is to eliminate the above-mentioned reducing substances by the simple Fehling test provided it is properly done, *i.e.* after boiling the solution and adding the urine drop by drop. Reboiling is not necessary, warming will do. If the reduction is rapid we may be pretty certain of the presence of glucose, but if it is slow and the precipitate yellow, instead of red, the fermentation test will verify. While the specific gravity of diabetic urine is usually high, it may be low if the absorption of nitrogenous material from the digestive tract is low. The quantity also is not invariably high. The total nitrogen of the urine should be increased on account of the greater ingestion of protein, but it becomes pathological when the body albumin is also excreted with the high sugar output. The greater the nitrogen loss the more the patient suffers. A high ammonia value means a severe case and the ammonia determination gives an accurate estimation of the acidosis present. We can predict the onset of coma by the urinary findings. The finding of beta-oxybutyric acid or diacetic acid in the urine should always serve as a danger signal The increase in the ammonia output is equally important. A sudden diminution or disappearance of glucose, together with turbidity from hyaline and granular casts and the appearance of albumin in urine previously free from it, are also danger signals. Lastly, he mentions the Cammidge reaction as a valuable indication of pancreatic disease which may be present in diabetes though he has had no experience with it in this disorder.

Postoperative Hematemesis.—After reporting a case of this dangerous complication occurring after fracture of several ribs, G. E. Potter remarks that in this case the transference of symptoms from the chest to the abdomen is clear when we recall the anatomic distribution of the anterior rami of the six lower intercostal nerves in the abdominal wall and parietal peritoneum as described by Ramstorm. The postoperative hematemesis is best explained, he says, by the theory of sepsis as suggested by W. L. Rodman. The hemorrhage here was from ulcers in the gastric mucosa which were apparently of recent formation and originated from the infected lung and pleura. The question is whether emboli carried the infection to the gastric mucosa or whether the infectious organisms alone were transported to and caused thrombi with subsequent emboli in the gastric vessels. The mortality of such cases is high and the treatment can only be symptomatic, as the bleeding is from numerous erosions in the stomach. The stomach should be washed out with a 2 per cent. solution of sodium bicarbonate at a temperature of from 100° to 120° F. till it returns clear, and this should be followed by 60 c.c. of a 1 to 1000 solution of adrenalin chloride. Rectal feeding, ice bag to the epigastrium, and subcutaneous or rectal gelatin solution injections may be useful. The patient should be kept as quiet as possible.

The Lancet, March 5, 1910.

The Treatment of Tuberculous Abscesses of Bony Origin by Conservative Methods.—Jacques Calve and H. J. Gauvain state that the first principle governing the treatment of tuberculous abscesses is the avoidance of their spontaneous opening and subsequent sinus formation. They especially consider abscesses in connection with tuberculous disease of the spine, hip, and knee joint. Their conservative method of treatment consists in aspiration, the technique of which is fully described. Among the long lists of chemical products that have been injected into cavities of cold abscesses they call special attention to iodoform dissolved in various vehicles. The indications for this method of treatment are summed up as follows: (1) When a simple aspiration is sufficient to empty the contents of the abscess, even though such aspirations may have to be repeated, a cure may be obtained without further operative treatment and without injection. (2) If in spite of repeated simple aspiration the pus collects again more abundantly each time, the abscess increases in size, and the walls do not show signs of becoming denser by the formation of fibrous tissue, then iodoform ether will be indicated on account of its drying and sclerosing properties. (3) If the contents of the abscess are caseous, then cautious injection of camphor-thymol-ether solution should be employed. (4) The abscess sometimes increases rapidly, is extensive, the tissues are being invaded, and the general condition of the patient is unsatisfactory. In this case one's first duty is to make good the defect in treatment. The oily mixture of iodoform, containing creosote and guaiacol, should be used. Three cardinal principles should be adopted: Maximum employment of general treatment; strict and uninterrupted immobilization in the horizontal position over a prolonged period, if the lesion is one of the spine, hip, or knee; the employment of aspirations with or without injection of modifying fluid. Cure takes place in from 95 to 98 per cent. of the cases so treated.

The Variations of Temperature in Phthisis During the Menstrual Period.—Cuthbert G. Welch has analyzed the records of 500 patients between the ages of 18 and 45 years suffering from tuberculosis and, for convenience sake, he divides them into three classes. In Class A (those with not more than one lobe affected) there were 284 cases. The changes most frequently found were a depression in the temperature, somewhat more marked but otherwise similar to that occurring in the healthy woman; except that the temperature fell on the first day, and not on the day preceding the flow; and, further, the progressive and preliminary rise in the intermenstrual period appeared to occur but rarely, being present in only three of his cases. In Class B (those with two lobes affected) there were 160 cases. A definite rise occurred in more than half of them. In Class C (advanced cases) there were 56 cases. A simple depression occurred in only 14.2 per cent. of the cases, a rise in 57 per cent. The fact that the temperature appeared to rise definitely in the more advanced and febrile cases would seem to indicate that rest in these cases should be more rigidly enforced at the periods, and it would be wise to postpone drawing inferences from the tempertaure chart in a case first seen during menstruation as to the nature and type of the lesion until the period is over, and the influence of menstruation upon the temperature can be eliminated.

A Case of Rheumatoid Arthritis Treated by Thyroid Extract.—George Steele-Perkins reports the case of a woman, 28 years old, with rheumatoid arthritis in both knee joints, with much thickening, and effusion into both joints. Most of the ordinary methods of treatment failed to give relief. Finding that her thyroid was small he commenced giving thyroid extract, with the result that, a month after, her knees in no way troubled her.

British Medical Journal, March 5, 1910.

Optic Neuritis, Choked Disc, or Papilledema.—Sir Victor Horsley considers the treatment, the localizing value, and the pathology of this condition and discusses the following points: 1, The localizing value of papilledema or optic neuritis; 2, the part of the disc which first becomes edematous as a consequence of increased intracranial pressure; 3, proof of Mr. Marcus Gunn's view of the mechanism whereby the macular or star figure is produced; 4, the phagocytes of the retina in neuroretinitis and their origin. The following is his summary: (1) The maximal intensity and age of the papilledema or optic neuritic in cases of increased intracranial tension is of the highest value in clinical localization of the lesion, and is isolateral with the maximal pressure effects of the latter. (2) Papilledema produced by increased intracranial tension commences at the upper border of the optic papilla, and invades last the inferior temporal quadrant. (3) The macular figure, as Mr. Gunn stated, is caused by tension lines centered at the fovea, the greatest stress being just beneath the intima. (4) The phagocytes of the retina consist of several kinds, as follows: (a) wander cells; (b) connective tissue corpuscles; (c) epithelioid corpuscles of the nerve fiber layer; (d) epithelioid corpuscles of the outer granule-layer—the two latter varieties being in close relation to the supporting fibers of Müller. Among eighteen unselected cases, in no less than two the correctness of the localizing diagnosis depended wholly on the degree of the neuritis.

The Action of Cutaneous Anesthetics.—A. Rendle Short and Walter Salisbury endeavored to determine whether the various drugs applied to the unbroken skin with a view to the relief of pain have the action attributed to them. They concerned themselves only with liniments, lotions, ointments, and other means of introducing drugs by absorption through the skin itself. The following preparations for this purpose are contained in the British Pharmacopeia: linimentum belladonnæ, emplastrum belladonnæ, unguentum belladonnæ, unguentum atropinæ, unguentum gallæ cum opio, linimentum opii, emplastrum opii, linimentum aconiti, unguentum aconitinæ, and unguentum cocainæ. They had no hesitation in saying that, as a result of their investigations, none of these has any anesthetic effect on the unbroken skin. They also claim that the time-honored custom of giving opium or belladonna suppositories after operations on the rectum is founded upon a misconception. Any effect they may have is due to the general action of the drug, not to its influence on the nerve-endings in the bowel. There is no drug in common use capable of acting as an anesthetic on the unbroken skin, except the ethyl-chloride spray, which freezes it. In the treatment of sprains, bruises, and neuralgia we must trust to other methods, such as counter-irritation, massage, and analgesics given hypodermically or by the mouth if necessary.

Infantile Glaucoma or Buphthalmia.—Wilfrid Allport reports the case of a child, three years old, who had a marked buphthalmos. The corneæ were considerably enlarged, and showed extensive nebulous opacities. The tension was high, photophobia was present, and the sight was seriously impaired. In April he performed anterior sclerotomy on the right eye; the Graefe knife was carried across the anterior chamber, and the point emerged through the sclera on the other side. By a few sawing movements the intercalary region was incised on both sides of the cornea, leaving, however, a bridge of sclera intact at the upper part. Unfortunately these incisions healed very rapidly and firmly, and the tension soon became as high as ever. He then decided to alter the procedure and, in the following June, he did an anterior sclerotomy on the other eye, but the incision was extended so as to cut entirely through the upper part of the intercalary region. The knife as it emerged through the sclera above the cornea was not allowed to cut through the conjunctiva, but this membrane was undermined for a few millimeters, producing a bridge of tissue which held the flap-like portion of the cornea in position. The idea of this operation was to obtain a scar at the filtration angle which would be sufficiently loose and porous to allow the intraocular fluid to escape through it under the conjunctiva, and so produce a permanent drain. The result more than fulfilled his expectations, the tension soon becoming normal, and the symptoms gradually abated. In September a similar operation was performed on the other eye with an equally satisfactory result.

Notes on a Case of Cyclophoria.—A. Allison Bradburne reports such a case. The patient wore glasses for distant vision which were perfectly correct, but when he came to read with them the rotation of the eyes which took place would lead to a want of parallelism of the lines of his book. These lines would, in fact, tend to cross when the images were fused, but as the brain would not tolerate double images it would make every effort to correct this want of alignment. This was overcome by a special effort on the part of the oblique muscles of the eyes, whose function it was to rotate the eyes. At first the extra exertion would entail little strain on the nervous output of energy; but as time went on its effects of the general nervous system would become more pronounced. The phenomenon of the sloping of the ground, which was noticed after near work, is explained by the cramped position into which the oblique muscles had brought the eyes, causing them to become fixed in a position which made them incorrect for the gaze when directed straight ahead. Some of the troubles complained of were caused by this

highly sensitive condition of his nerves to any external irritants.

Münchener medizinische Wochenschrift, February 22, 1910.

A Typhoid Epidemic with an Initial Hemorrhagic Exanthem.—Curschmann refers to the rarity of a hemorrhagic irruption in typhoid fever. When such a rash occurs it is usually towards the end of the disease and indicates a fatal outcome. He then reports an epidemic in which the character of the disease differed from the usual in that the hemorrhagic exanthem appeared during the early stage in cases of moderate severity. The epidemic occurred in one family, mother and six children being attacked. In all the onset was acute and stormy, usually with vomiting and in two instances with a chill. The fever rose rapidly and reached its maximum in two days. On the second or third day in every case there appeared more or less numerous hemorrhagic, bluish patches on the chest, shoulders, and arms, only in two instances on the abdomen. The spots did not disappear on pressure and left brown staining. The fever in most cases was continuous, in one only being remittent. In the two older children defervescence was by crisis, in the four younger by lysis. In the case of the mother the pulse was slow, in the children rapid. The diazo reaction was positive in the mother, negative in the children. The differential diagnosis between typhoid and typhus is discussed, the diagnosis of typhoid being based upon the following points: There was complete absence of delirium in all cases. The eruption was petechial from the onset, whereas the typhus rash begins as an erythema and later becomes hemorrhagic. There was a marked leucopenia in all the cases. In five of the seven cases the Ficker modification of the agglutination test was positive, and in two cases typhoid bacilli was isolated from the stools. Finally the father of the family at the same time suffered from a typical attack of typhoid fever, with the usual roseola, and died, the autopsy showing typical typhoid lesions in the intestines.

Edema Neonatorum.—Schridde reports some careful pathological observations on three cases of edema neonatorum. The placenta and the umbilical cord showed very marked edema. The edema was general and extreme, being especially pronounced in the upper extremities and the head. On cutting through the edematous skin the subcutaneous tissue was seen to be laden with a thick layer of clear, light yellow, gelatinous material, with fine white lines of fat running through it. The abdomen was greatly distended, the circumference varying from 41 to 43.5 c.c., and in the peritoneal cavity was a large quantity of acitic fluid. There was also excess of fluid in the pericardium and a decided pleural effusion. The spleen was greatly enlarged, in one case reaching to the symphysis. On section the splenic pulp was of a homogeneous gray red color and no malphighian bodies were seen. The liver was less markedly enlarged. On section it was of a brown color. The kidneys were of normal size, but contained many grayish streaks running through them in all directions, and hemorrhagic areas. The mesenteric lymph glands were greatly enlarged. The heart was markedly hypertrophied. The blood vessels showed no changes. The other organs showed no gross lesions. No signs of syphilis could be found. On microscopic examination the spleen was seen to be composed almost entirely of myeloid material. There were many foci of erythroblasts with basophilic protoplasm, and activity dividing nuclei. There were also larger foci of leucocytes, consisting largely of myelocytes. The lymphatic tissue was wholly undeveloped. Relatively frequently were seen spleen cells containing iron pigment. The liver, too, showed the picture of a blood forming organ with foci of erythroblasts. Myeloid cells appeared as in the spleen. The liver showed a marked deposit of hemosiderin. There were no signs of congestion. The kidney changes resembled those of the liver and spleen. The kidney epithelium contained a granular, greenish yellow pigment, which gave no iron reaction. The bone marrow showed an increase of myeloblasts over the myelocytes. The heart muscle was filled with a lipochrome pigment. The placenta and cord showed nothing more than edema. Careful search for spirochete was fruitless. The blood picture under low magnification closely resembled myelogenous leukemia. Under higher power it was seen that an enormous number of erythroblasts were present, showing an extreme degree of myotic figures. Next to these came myeloblasts and myelocytes. Lymphocytes and polymorphonuclear leucocytes were conspicuous by their absence. Among the red cells were many megalocytes. The entire picture showed the presence of a primary anemia. No light is thrown upon the etiology of the disease except that there was no sign of syphilis in any of the three cases.

Deutsche medizinische Wochenschrift, February 24, 1910.

Bacterial Findings in Cheese Poisoning.—H. Dodd reports upon five persons who were taken ill three to six hours after eating cheese with nausea, vomiting, abdominal pain, and diarrhea. Chemical examinations for toxins, poisonous metals, etc., were negative. Bacterial examination showed the presence in nearly a pure culture of a bacterium having the morphological and biological characteristics of *Bacterium acidi lactici* (Hueppe) and was pathogenic in the intestines of rabbits.

French and Italian Journals.

Adiposogenital Hypophysis Syndrome.—P. E. Laonois and M. Clerét give the adiposogenital syndrome as the indication of the presence of a tumor of the hypophysis. There are three fundamental symptoms; increase of adipose, genital atrophy, and presence of tumor symptoms. The fat is everywhere increased immensely, within the body and on the surface. Rolls of fat cover the chest, breasts, abdomen, and thighs, and are deposited in the omentum and mesenteries. The genitals are atrophied in both sexes, and frigidity is the rule. Menstruation is late in establishment and the menopause occurs early; the flow is scanty and irregular in the adult. The presence of a tumor is shown by the usual symptoms of intracranial pressure—headache, convulsions, projectile vomiting, loss of memory, torpor of the intellect, and dimness of vision due to optic atrophy. The use of radiography will enable us to see the shadow of the tumor in the region of the hypophysis.—*Gazette des Hôpitaux*, January 18, 1910.

Treatment of Salpingo-oöphoritis, Fibromata, and Scleroses of the Uterus by the Ultra-penetrating Radium Rays.—Henri Cheron advocates the use of the ultra-penetrating rays of radium in all cases of salpingo-oöphoritis in which the pus collections do not need immediate evacuation on account of their size, and the bad general condition of the patient. They should also be tried before operation in all fibromata of moderate size which are giving trouble, when it is not desirable to retain the ovarian function. Their action on the ovaries is to sterilize them and occasion an early menopause. It is in this way that the rays have their effect on the fibromata. When no effect is obtained in this way the case should be given over to operation if pressure symptoms are present. The treatment is given with small tubes of bromide or sulphate of radium, wrapped in tarletan, so as to cut off all the rays except γ and β rays, and prevent burning. The tubes may be placed in the vagina, cervix, or the body of the uterus. In all such cases this treatment should precede operation.—*L'Obstetrique*, November, 1909.

Development of the Viscera in the Fetus.—Francesco Valtorta desires to establish a standard of the normal measurements and weights of the viscera, with which we can compare the conditions found in abnormal fetuses. He made careful measurements of all the fetuses that died from women who were brought to the Milan Maternity during labor, thus establishing the standard from fetuses that actually died during labor. He gives the average measurements of brain, heart, lungs, thymus, liver, spleen, pancreas, kidneys, stomach, intestines, testicles, uterus, and ovaries. He finds that the thorax is flattened from side to side; when this is the case it is due to lack of development of the organs of respiration. The chest is broad below on account of the relatively enormous size of the liver and abdominal viscera. The organs that are most developed are those that must be used immediately after birth.—*Annali di Ostetricia e Ginecologia*, December, 1909.

Contribution to the Study of Ovarian Endothelioma.—Piero Ligabue states that endothelioma may occur in any of the organs usually attacked by carcinoma. It is essentially a malignant growth, the prognosis is bad, and treatment is operative. The tissues found in the endotheliomata are very varied. The chief constituents are fibrous tissue with wide connective tissue spaces, in which are found large, endothelial cells, developed from the endothelium of the reticulum. They are found in large or small groups near the periphery of the growth. There seems to be no hereditary element in the etiology. They occur at any time of life, but when attacking the ovary they occur especially between the ages of forty and fifty. They do not cause metorrhagia or menorrhagia, and pain, ascites, and edema may be present. The power of metastasis is slight. They may be extremely adherent to other organs. The author gives the history and the histological examination of an ovarian endothelioma operated on by him.—*Il Policlinico*, Jan. 1, 1910.

Book Reviews.

A Handbook of Medical Diagnosis. In Four Parts. I. Medical Diagnosis in General. II. The Methods and Their Immediate Results. III. Symptoms and Signs. IV. The Clinical Applications. For the use of students and practitioners. By J. C. Wilson, A.M., M.D., Professor of the Practice of Medicine and Clinical Medicine in the Jefferson Medical College, and Physician to Its Hospital; Physician to the Pennsylvania Hospital; Physician in Chief to the German Hospital, Philadelphia. Philadelphia and London: J. B. Lippincott Co., 1909.

It has been said by one wise in medical lore that most books are written either by young men who have not had time to learn anything, or by old men who have forgotten all that they knew. It is a pleasure to record that the eminent author of this volume cannot be included in either of these classes, for he seems to have learned much and forgotten little during his many years of clinical teaching. Fourteen hundred and twelve closely printed pages will certainly testify to the amount of his knowledge.

The book is divided for convenience into four parts; the first part on medical diagnosis in general; the second on special methods of diagnosis and their immediate results; the third on symptoms and physical signs, and the fourth on the clinical application of the facts obtained. The chapter on general considerations of medical diagnosis should be read by every student beginning his work in the observation of the sick. In it the writer pleads for thoroughness and care rather than brilliancy, and expresses the feeling that the art of diagnosis is in observation. He says with much truth that errors occur far more commonly from incomplete observation than from want of knowledge, a fact which all of us can verify from our experience with our medical colleagues, the careful painstaking ones often surpassing in the long run the brilliant masters of "snap diagnosis." Besides advising constant attendance in the post-mortem room, the surgical operating theater is also recommended as an excellent place to study lesions of the abdominal and thoracic organs, and it is suggested to the physician that he spend as much time as possible in close proximity to these convenient autopsies *in vivo*. The next section, on the medical topography of the body, covers the usual ground in a more or less conventional fashion, though the author prefers the use of midclavicular line to that of mamillary line. In Fig. 26, showing the position of the spleen, the artist has placed the organ too high, its position does not correspond to the text description. The examination of the patient and case-taking are next considered, and a convenient system of abbreviations is given for recording physical signs. General physical diagnosis is then taken up and covered very clearly. In discussing low blood pressure, Addison's disease might advantageously be added to the list of those showing the phenomenon. Much stress is laid upon the value of immediate percussion. In the section on the examination of the stomach and intestine a somewhat condensed description of the methods of chemical analysis of the gastrointestinal contents is given. Uffelmann's test is included, though it is one of the least valuable of the many tests for lactic acid. The work of Gross can hardly have been taken into account, judging from the sentence in the section on the examination of the feces: "Digestive ferments are not found." Neither is mention made of the benzidin test for blood. The section on the technique of the morphological examnation of the blood is also somewhat unsatisfactory. Under the subject of the Jenner stain it is said that a deposit of dark granules on the blood film is often observed. Such a deposit is the fault of the technique in allowing the stain to dry on the slide, and is never seen if the original directions are carried out. The Giemsa blood stain is also not given, though the old Chenzinsky and the Ehrlich dahlia stain for basophiles are introduced. There is a fairly good colored plate showing the morphology of the white and red cells in health and disease, but no statement is made as to the stain employed. Rosenberger's statement that tubercle bacilli are found in large quantities in the blood of persons with tuberculosis is accepted without challenge. The statement is also made that fresh unstained blood is more satisfactory than stained blood in examining for malarial parasites, because it enables the examiner to observe the activity of the organisms. In such an examination the difficulty is usually to find an organism and identify it positively, and this identification, especially in estivo-autumnal malarias, is very greatly aided by a good chromatin stain, such as can now be readily obtained with any of the standard staining mixtures.

The section on the examination of the urine is good, though there are errors both in the description of the Folin method of determining uric acid, and in the method for the quantitative determination of chlorides. It seems questionable whether it would not be better to leave such laboratory technical methods to the special treatises, and not to attempt to cover these often highly specialized procedures. It is only just to say, however, that this chapter was not written by the senior author. Following this section comes another on the examination of the nervous system, which is very satisfactory, with good illustrations of the methods of obtaining the various reflexes. The part on the examination of the eye is admirably illustrated by a series of colored drawings of various changes in the fundus. A short sketch with a few illustrations is given of the methods and results of examination with the *x*-ray. This brings us to Part III of the work, that is, the general consideration of symptoms and signs which may lead to a diagnosis. A number of excellent photographs give fresh interest to the section on facies. Joint changes are also well pictured. On the whole, this part may be considered one of the best in the book. The last section deals with the clinical applications to diagnosis. Here the senior author's long experience in hospital wards gives to the text a richness of description and a clearness and practical value which are as valuable as they are rare in medical writings. The illustrative photographs throughout are excellent, and have the additional quality of not being hackneyed copies from other writers. The final portion on the nervous system is perhaps not quite so strong as the rest, but the changes in our knowledge of the subject are so rapid in many cases that it is difficult to treat of many of the doubtful points. In illustration of this we need quote but one sentence, under the discription of caisson disease: "The fanciful theory that air bubbles or air emboli cause the softening (in the cord) need not be discussed here."

Taking the book as a whole, however, it seems to the reviewer that it is, despite the shortcomings mentioned, one of the very best and soundest volumes published on medical diagnosis, useful to the student and invaluable to the practitioner.

Das Geburtshilfliche Seminar. Praktische Geburtshilfe in 18 Vorlesungen für Arzte und Studierende, von Dr. Wilhelm Liepmann, Privatdocent für Geburtshilfe und Gynäkologie an der Friedrich Wilhelms Universität. Direktor der Frauenklinik des Deutschen Bundes für Mutterschutz in Berlin. Berlin: Verlag von August Hirschwald, 1910.

In this very excellent manual intended for students and practitioners the author has further extended the system of obstetrical instruction first developed by Prof. Leopold of Dresden, and the lectures of the present series (seminaristischen Uebungen) are set down in the exact colloquial form in which they were delivered by the writer. The latter in each lecture proceeds to state in detail the history of a clinical case, after which the auditors give their opinions as to its prognosis and treatment. In this way it is believed that the student will conform to the habit of formulating his own views, which are in turn reviewed and developed by the instructor. In other words, this is a true "seminar" as distinguished from a didactic lecture, and in reading through the various chapters of Liepmann's book it is quite obvious that the method has much merit. The lectures, which number eighteen, include only the practical phases of obstetrics and are thoroughly well illustrated by a sufficient number of outline drawings, for which an additional word of commendation is demanded. They are simple and unadorned; they illustrate certain obstetrical conditions and are not works of art. Both the book and its make-up are worthy of attention and emulation.

Die Impotenz des Mannes. Für Ärzte dargestellt von Dr. P. Orlowski, Spezialarzt in Berlin. Zweite bedeutend erweiterte Auflage mit 22 Abbildungen in Text und 3 farb. Tafeln. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.
